## Chapter 1

## Probabilities and random variables

Probability theory is a systematic method for describing randomness and uncertainty. It prescribes a set of mathematical rules for manipulating and calculating probabilities and expectations. It has been applied in many areas: gambling, insurance, finance, the study of experimental error, statistical inference, and more.

One standard approach to probability theory (but not the only approach) starts from the concept of a sample space, which is an exhaustive list of possible outcomes in an experiment or other situation where the result is uncertain. Subsets of the list are called events. For example, in the very simple situation where 3 coins are tossed, the sample space might be

$$
S=\{h h h, h h t, h t h, h t t, t h h, t h t, t t h, t t t\} .
$$

There is an event corresponding to "the second coin landed heads", namely,

$$
\{h h h, h h t, t h h, t h t\} .
$$

Each element in the sample space corresponds to a uniquely specified outcome.

Notice that $S$ contains nothing that would specify an outcome like "the second coin spun 17 times, was in the air for 3.26 seconds, rolled 23.7 inches when it landed, then ended with heads facing up". If we wish to contemplate such events we need a more intricate sample space $S$. Indeed, the choice of $S$-the detail with which possible outcomes are described-depends on the sort of events we wish to describe.

In general, a sample space can make it easier to think precisely about events, but it is not always essential. It often suffices to manipulate events via a small number of rules (to be specified soon) without explicitly identifying the events with subsets of a sample space.

If the outcome of the experiment corresponds to a point of a sample space belonging to some event, one says that the event has occurred. For example, with the outcome hhh each of the events \{no tails\}, \{at least one head $\}$, \{more heads than tails\} occurs, but the event \{even number of heads\} does not.

The uncertainty is modelled by a probability assigned to each event. The probabibility of an event $E$ is denoted by $\mathbb{P} E$. One popular interpretation of $\mathbb{P}$ (but not the only one) is as a long run frequency: in a very large
number ( $N$ ) of repetitions of the experiment,
(number of times $E$ occurs) $/ N \approx \mathbb{P} E$,

More about independence soon.

$<1>$
Note: The examples are collected together at the end of each chapter
provided the experiments are independent of each other.
As many authors have pointed out, there is something fishy about this interpretation. For example, it is difficult to make precise the meaning of "independent of each other" without resorting to explanations that degenerate into circular discussions about the meaning of probability and independence. This fact does not seem to trouble most supporters of the frequency theory. The interpretation is regarded as a justification for the adoption of a set of mathematical rules, or axioms. See Chapter 2 for an alternative interpretation, based on fair prices.

The first four rules are easy to remember if you think of probability as a proportion. One more rule will be added soon.

## Rules for probabilities.

(P1) $0 \leq \mathbb{P} E \leq 1$ for every event $E$.
(P2) For the empty subset $\emptyset(=$ the "impossible event"), $\mathbb{P} \emptyset=0$,
(P3) For the whole sample space ( $=$ the "certain event"), $\mathbb{P} S=1$.
(P4) If an event $E$ is a disjoint union of a sequence of events $E_{1}, E_{2}, \ldots$ then $\mathbb{P} E=\sum_{i} \mathbb{P} E_{i}$.

Example. Find $\mathbb{P}\{$ at least two heads\} for the tossing of three coins.
Probability theory would be very boring if all problems were solved like that: break the event into pieces whose probabilities you know, then add. Things become much more interesting when we recognize that the assignment of probabilities depends on what we know or have learnt (or assume) about the random situation. For example, in the last problem we could have written
$\mathbb{P}\{$ at least two heads $\mid$ coins fair, "independence," $\ldots\}=\ldots$
to indicate that the assignment is conditional on certain information (or assumptions). The vertical bar stands for the word given; that is, we read the symbol as probability of at least two heads given that ...

If the conditioning information is held fixed throughout a calculation, the conditional probabilities $\mathbb{P}(\ldots \mid$ info ) satisfy rules (P1) through (P4). For example, $\mathbb{P}(\emptyset \mid$ info $)=0$, and so on. In that case one usually doesn't bother with the "given ...", but if the information changes during the analysis the conditional probability notation becomes most useful.

The final rule for (conditional) probabilities lets us break occurrence of an event into a succession of simpler stages, whose conditional probabilities might be easier to calculate or assign. Often the successive stages correspond to the occurrence of each of a sequence of events, in which case the notation is abbreviated:
$\mathbb{P}(\ldots \mid$ event $A$ and event $B$ have occurred and previous info $)$
or
$\mathbb{P}(\ldots \mid A \cap B \cap$ previous info $) \quad$ where $\cap$ means intersection
or
$\mathbb{P}(\ldots \mid A, B$, previous info $)$
or
$\mathbb{P}(\ldots \mid A \cap B) \quad$ if the "previous info" is understood.
or
$\mathbb{P}(\ldots \mid A B) \quad$ where $A B$ is an abbreviation for $A \cap B$.

The commas in the third expression are open to misinterpretation, but convenience recommends the more concise notation.

Remark. I must confess to some inconsistency in my use of parentheses and braces. If the "..." is a description in words, then $\{\ldots\}$ denotes the subset of $S$ on which the description is true, and $\mathbb{P}\{\ldots\}$ or $\mathbb{P}\{\cdots \mid$ info $\}$ seems the natural way to denote the probability attached to that subset. However, if the "..." stand for an expression like $A \cap B$, the notation $\mathbb{P}(A \cap B)$ or $\mathbb{P}(A \cap B \mid$ info $)$ looks nicer to me. It is hard to maintain a convention that covers all cases. You should not attribute much significance to differences in my notation involving a choice between parentheses and braces.

## Rule for conditional probability.

(P5) : if $A$ and $B$ are events then

$$
\mathbb{P}(A \cap B \mid \text { info })=\mathbb{P}(A \mid \text { info }) \cdot \mathbb{P}(B \mid A, \text { info }) .
$$

The frequency interpretation might make it easier for you to appreciate this rule. Suppose that in $N$ "independent" repetitions (given the same initial conditioning information) $A$ occurs $N_{A}$ times and $A \cap B$ occurs $N_{A \cap B}$ times. Then, for big $N$,

$$
\mathbb{P}(A \mid \text { info }) \approx N_{A} / N \quad \text { and } \quad \mathbb{P}(A \cap B \mid \text { info }) \approx N_{A \cap B} / N
$$

If we ignore those repetitions where A fails to occur then we have $N_{A}$ repetitions given the original information and occurrence of $A$, in $N_{A \cap B}$ of which the event $B$ also occurs. Thus $\mathbb{P}(B \mid A$, info $) \approx N_{A \cap B} / N_{A}$. The rest is division.

In my experience, conditional probabilities provide a more reliable method for solving problems traditionally handled by counting arguments (Combinatorics). I find it hard to be consistent about how I count, to make sure every case is counted once and only once, to decide whether order should matter, and so on. The next Example illustrates my point.

Example. What is the probability that a hand of 5 cards contains four of a kind?

I wrote out many of the gory details to show you how the rules reduce the calculation to a sequence of simpler steps. In practice, one would be less explicit, to keep the audience awake.

The statement of the next example is taken verbatim from the delightful Fifty Challenging Problems in Probability by Frederick Mosteller, one of my favourite sources for elegant examples. One could learn a lot of probability by trying to solve all fifty problems. The underlying question has resurfaced in recent years in various guises. See
http://en.wikipedia.org/wiki/Monty_Hall_problem
http://en.wikipedia.org/wiki/Marilyn_vos_Savant\#The_Monty_Hall_problem
to understand why probabilistic notation is so valuable. The lesson is: Be prepared to defend your assignments of conditional probabilities.

Example. Three prisoners, A, B, and C, with apparently equally good records have applied for parole. The parole board has decided to release two of the three, and the prisoners know this but not which two. A warder friend of prisoner A knows who are to be released. Prisoner A realizes that it would be unethical to ask the warder if he, A , is to be released, but thinks of asking for the name of one prisoner other than himself who is to be released.

He thinks that before he asks, his chances of release are $2 / 3$. He thinks that if the warder says "B will be released," his own chances have now gone down to $1 / 2$, because either A and B or B and C are to be released. And so A decides not to reduce his chances by asking. However, A is mistaken in his calculations. Explain.

You might have the impression at this stage that the first step towards the solution of a probability problem is always an explicit listing of the sample space specification of a sample space. In fact that is seldom the case. An assignment of (conditional) probabilities to well chosen events is usually enough to set the probability machine in action. Only in cases of possible confusion (as in the last Example), or great mathematical precision, do I find a list of possible outcomes worthwhile to contemplate. In the next Example construction of a sample space would be a nontrivial exercise but conditioning helps to break a complex random mechanism into a sequence of simpler stages.
$<4>$ Example. Imagine that I have a fair coin, which I toss repeatedly. Two players, M and R, observe the sequence of tosses, each waiting for a particular pattern on consecutive tosses: M waits for hhh, and $R$ waits for tthh. The one whose pattern appears first is the winner. What is the probability that M wins?

In both Examples $<3>$ and $<4>$ we had situations where particular pieces of information could be ignored in the calculation of some conditional probabilities,

$$
\begin{aligned}
& \mathbb{P}\left(\mathcal{A} \mid B^{*}\right)=\mathbb{P}(\mathcal{A}), \\
& \mathbb{P}(\text { next toss a head } \mid \text { past sequence of tosses })=1 / 2 .
\end{aligned}
$$

Both situations are instances of a property called independence.

Definition. Call events $E$ and $F$ conditionally independent given a particular piece of information if

$$
\mathbb{P}(E \mid F, \text { information })=\mathbb{P}(E \mid \text { information }) .
$$

If the "information" is understood, just call E and F independent.

The apparent asymmetry in the definition can be removed by an appeal to rule P5, from which we deduce that

$$
\mathbb{P}(E \cap F \mid \text { info })=\mathbb{P}(E \mid \text { info }) \mathbb{P}(F \mid \text { info })
$$

for conditionally independent events $E$ and $F$. Except for the conditioning information, the last equality is the traditional definition of independence. Some authors prefer that form because it includes various cases involving events with zero (conditional) probability.

Conditional independence is one of the most important simplifying assumptions used in probabilistic modeling. It allows one to reduce consideration of complex sequences of events to an analysis of each event in isolation. Several standard mechanisms are built around the concept. The prime example for these notes is independent "coin-tossing": independent repetition of a simple experiment (such as the tossing of a coin) that has only two possible outcomes. By establishing a number of basic facts about coin tossing I will build a set of tools for analyzing problems that can be reduced to a mechanism like coin tossing, usually by means of well-chosen conditioning.
$<5>\quad$ Example. Suppose a coin has probability $p$ of landing heads on any particular toss, independent of the outcomes of other tosses. In a sequence of such tosses, show that the probability that the first head appears on the $k$ th toss is $(1-p)^{k-1} p$ for $k=1,2, \ldots$.

The discussion for the Examples would have been slightly neater if I had had a name for the toss on which the first head occurs. Define

$$
X=\text { the position at which the first head occurs. }
$$

Then I could write

$$
\mathbb{P}\{X=k\}=(1-p)^{k-1} p \quad \text { for } k=1,2, \ldots
$$

The $X$ is an example of a random variable.
Formally, a random variable is just a function that attaches a number to each item in the sample space. Typically we don't need to specify the sample space precisely before we study a random variable. What matters more is the set of values that it can take and the probabilities with which it takes those values. This information is called the distribution of the random variable.

For example, a random variable $Z$ is said to have a geometric(p) distribution if it can take values $1,2,3, \ldots$ with probabilities

$$
\mathbb{P}\{Z=k\}=(1-p)^{k-1} p \quad \text { for } k=1,2, \ldots
$$

The result from the last example asserts that the number of tosses required to get the first head has a geometric $(p)$ distribution.

Remark. Be warned. Some authors use geometric $(p)$ to refer to the distribution of the number of tails before the first head, which corresponds to the distribution of $Z-1$, with $Z$ as above.

Why the name "geometric"? Recall the geometric series,

$$
\sum_{k=0}^{\infty} a r^{k}=a /(1-r) \quad \text { for }|r|<1
$$

Notice, in particular, that if $0<p \leq 1$, and $Z$ has a $\operatorname{geometric}(p)$ distribution,

$$
\sum_{k=1}^{\infty} \mathbb{P}\{Z=k\}=\sum_{j=0}^{\infty} p(1-p)^{j}=1
$$

What does that tell you about coin tossing?
The final example for this Chapter, whose statement is also borrowed verbatim from the Mosteller book, is built around a "geometric" mechanism.
$<6>$ Example. A, B, and C are to fight a three-cornered pistol duel. All know that A's chance of hitting his target is 0.3 , C's is 0.5 , and B never misses. They are to fire at their choice of target in succession in the order A, B, C, cyclically (but a hit man loses further turns and is no longer shot at) until only one man is left unhit. What should A's strategy be?

## Things to remember.

- S

, and the five rules for manipulating (conditional) probabilities.
- Conditioning is often easier, or at least more reliable, than counting.
- Conditional independence is a major simplifying assumption of probability theory.
- What is a random variable? What is meant by the distribution of a random variable?
- What is the geometric $(p)$ distribution?

## References

Mosteller, F. (1987). Fifty Challenging Problems in Probability with Solutions. New York: Dover.

## Example 1.

Find $\mathbb{P}$ \{at least two heads $\}$ for the tossing of three coins. Use the sample space

$$
S=\{h h h, h h t, h t h, h t t, t h h, t h t, t t h, t t t\} .
$$

If we assume that each coin is fair and that the outcomes from the coins don't affect each other ("independence"), then we must conclude by symmetry ("equally likely") that

$$
\mathbb{P}\{h h h\}=\mathbb{P}\{h h t\}=\cdots=\mathbb{P}\{t t t\} .
$$

By rule P 4 these eight probabilities add to $\mathbb{P} S=1$; they must each equal $1 / 8$. Again by P4,

$$
\mathbb{P}\{\text { at least two heads }\}=\mathbb{P}\{h h h\}+\mathbb{P}\{h h t\}+\mathbb{P}\{h t h\}+\mathbb{P}\{t h h\}=1 / 2
$$

## Example 2.

What is the probability that a hand of 5 cards contains four of a kind?
Let us assume everything fair and aboveboard, so that simple probability calculations can be carried out by appeals to symmetry. The fairness assumption could be carried along as part of the conditioning information but it would just clog up the notation to no useful purpose.

I will consider the ordering of the cards within the hand as significant. For example, $(7 \boldsymbol{\ell}, 3 \diamond, 2 \circlearrowleft, K \bigcirc, 8 \circlearrowleft)$ will be a different hand from $(K \circlearrowleft, 7 \boldsymbol{\ell}, 3 \diamond, 2 \circlearrowleft, 8 \circlearrowleft)$.

Start by breaking the event of interest into 13 disjoint pieces:

$$
\{\text { four of a kind }\}=\bigcup_{i=1}^{13} F_{i}
$$

where

$$
\begin{aligned}
F_{1}= & \{\text { four aces, plus something else }\} \\
F_{2}= & \{\text { four twos, plus something else }\} \\
& \vdots \\
F_{13}= & \{\text { four kings, plus something else }\} .
\end{aligned}
$$

By symmetry each $F_{i}$ has the same probability, which means we can concentrate on just one of them.

$$
\mathbb{P}\{\text { four of a kind }\}=\sum_{1}^{13} \mathbb{P} F_{i}=13 \mathbb{P} F_{1} \quad \text { by rule } \mathrm{P} 4 \text {. }
$$

Now break $F_{1}$ into simpler pieces, $F_{1}=\cup_{j=1}^{5} F_{1 j}$, where

$$
F_{1 j}=\{\text { four aces with jth card not an ace }\} .
$$

Again by disjointness and symmetry, $\mathbb{P} F_{1}=5 \mathbb{P} F_{1,1}$.
Decompose the event $F_{1,1}$ into five "stages", $F_{1,1}=N_{1} \cap A_{2} \cap A_{3} \cap A_{4} \cap A_{5}$, where

$$
N_{1}=\{\text { first card is not an ace }\} \quad \text { and } \quad A_{1}=\{\text { first card is an ace }\}
$$

and so on. To save on space, I will omit the intersection signs, writing $N_{1} A_{2} A_{3} A_{4}$ instead of $N_{1} \cap A_{2} \cap A_{3} \cap A_{4}$, and so on. By rule P5,

$$
\begin{aligned}
\mathbb{P} F_{1,1} & =\mathbb{P} N_{1} \mathbb{P}\left(A_{2} \mid N_{1}\right) \mathbb{P}\left(A_{3} \mid N_{1} A_{2}\right) \ldots \mathbb{P}\left(A 5 \mid N_{1} A_{2} A_{3} A_{4}\right) \\
& =\frac{48}{52} \times \frac{4}{51} \times \frac{3}{50} \times \frac{2}{49} \times \frac{1}{48} .
\end{aligned}
$$

Thus

$$
\mathbb{P}\{\text { four of a kind }\}=13 \times 5 \times \frac{48}{52} \times \frac{4}{51} \times \frac{3}{50} \times \frac{2}{49} \times \frac{1}{48} \approx .00024
$$

Can you see any hidden assumptions in this analysis?
Which sample space was I using, implicitly? How would the argument be affected if we took $S$ as the set of all of all $\binom{52}{5}$ distinct subsets of size 5 , with equal probability on each sample point? That is, would it matter if we ignored ordering of cards within hands?

## Example 3.

(The Prisoner's Dilemma-borrowed from Mosteller, 1987)
It is quite tricky to argue through this problem without introducing any notation, because of some subtle distinctions that need to be maintained.

The interpretation that I propose requires a sample space with only four items, which I label suggestively
$a B=$ both $A$ and $B$ to be released, warder must say $B$
$\mathrm{aC}=$ both A and C to be released, warder must say C
$\mathrm{Bc}=$ both B and C to be released, warder says B
$\mathrm{bC}=$ both B and C to be released, warder says C .

There are three events to be considered

$$
\begin{aligned}
\mathcal{A} & =\{\text { A to be released }\}=\{\boxed{a B}, \boxed{a C}\} \\
\mathcal{B} & =\{\mathrm{B} \text { to be released }\}=\{\boxed{\mathrm{aB}}, \boxed{\mathrm{Bc}}, \boxed{\mathrm{bC}}\} \\
\mathcal{B}^{*} & =\{\text { warder says B to be released }\}=\{\boxed{\mathrm{aB}}, \boxed{\mathrm{Bc}}\} .
\end{aligned}
$$

Apparently prisoner A thinks that $\mathbb{P}\left(\mathcal{A} \mid \mathcal{B}^{*}\right)=1 / 2$.
How should we assign probabilities? The words "equally good records" suggest (compare with Rule P4)

$$
\begin{aligned}
& \mathbb{P}\{\mathrm{A} \text { and } \mathrm{B} \text { to be released }\} \\
& =\mathbb{P}\{\mathrm{B} \text { and } \mathrm{C} \text { to be released }\} \\
& =\mathbb{P}\{\mathrm{C} \text { and } \mathrm{A} \text { to be released }\} \\
& =1 / 3
\end{aligned}
$$

That is,

$$
\mathbb{P}\{\mathrm{aB}\}=\mathbb{P}\{\mathrm{aC}\}=\mathbb{P}\{\mathrm{Bc}\}+\mathbb{P}\{\mathrm{bC}\}=1 / 3 .
$$

What is the split between $\overline{\mathrm{Bc}}$ and bC ? I think the poser of the problem wants us to give $1 / 6$ to each outcome, although there is nothing in the wording of the problem requiring that allocation. (Can you think of another plausible allocation that would change the conclusion?)

With those probabilities we calculate

$$
\begin{aligned}
\mathbb{P} \mathcal{A} \cap \mathcal{B}^{*} & =\mathbb{P}\{\mathrm{aB}\}=1 / 3 \\
\mathbb{P} \mathcal{B}^{*} & =\mathbb{P}\{\mathrm{aB}\}+\mathbb{P}\{\mathrm{Bc}\}=1 / 3+1 / 6=1 / 2,
\end{aligned}
$$

from which we deduce (via rule P5) that

$$
\mathbb{P}\left(\mathcal{A} \mid \mathcal{B}^{*}\right)=\frac{\mathbb{P} \mathcal{A} \cap \mathcal{B}^{*}}{\mathbb{P}^{*} \mathcal{B}^{*}}=\frac{1 / 3}{1 / 2}=2 / 3=\mathbb{P} \mathcal{A} .
$$

The extra information $\mathcal{B}^{*}$ should not change prisoner A's perception of his probability of being released.

Notice that

$$
\mathbb{P}(\mathcal{A} \mid \mathcal{B})=\frac{\mathbb{P} \mathcal{A} \cap \mathcal{B}}{\mathbb{P} \mathcal{B}}=\frac{1 / 3}{1 / 2+1 / 6+1 / 6}=1 / 2 \neq \mathbb{P} \mathcal{A} .
$$

Perhaps A was confusing $\mathbb{P}\left(\mathcal{A} \mid \mathcal{B}^{*}\right)$ with $\mathbb{P}(\mathcal{A} \mid \mathcal{B})$.

The problem is more subtle than you might suspect. Reconsider the conditioning argument from the point of view of prisoner C, who overhears the conversation between A and the warder. With $\mathcal{C}$ denoting the event

$$
\{\mathrm{C} \text { to be released }\}=\{\widehat{\mathrm{aC}}, \mathrm{Bc}, \boxed{\mathrm{bC}}\},
$$

he would calculate a conditional probability

$$
\mathbb{P}\left(\mathcal{C} \mid \mathcal{B}^{*}\right)=\frac{\mathbb{P}\{\overline{\mathrm{Bc}}\}}{\mathbb{P} \mathcal{B}^{*}}=\frac{1 / 6}{1 / 2} \neq \mathbb{P C} .
$$

The warder might have nominated C as a prisoner to be released. The fact that he didn't do so conveys some information to C. Do you see why A and C can infer different information from the warder's reply?

## Example 4.

Here is a coin tossing game that illustrates how conditioning can break a complex random mechanism into a sequence of simpler stages. Imagine that I have a fair coin, which I toss repeatedly. Two players, M and R, observe the sequence of tosses, each waiting for a particular pattern on consecutive tosses:

M waits for hhh and $\quad R$ waits for tthh.
The one whose pattern appears first is the winner. What is the probability that M wins?

For example, the sequence ththhttthh ... would result in a win for R, but ththhthhh... would result in a win for M.

You might imagine that M has the advantage. After all, surely it must be easier to get a pattern of length 3 than a pattern of length 4 . You'll discover that the solution is not that straightforward.

The possible states of the game can be summarized by recording how much of his pattern each player has observed (ignoring false starts, such as hht for M, which would leave him back where he started, although R would
have matched the first t of his pattern.).

| States | M partial pattern | R partial pattern |
| :---: | :---: | :---: |
| S | - | - |
| H | h | - |
| T | - | t |
| TT | - | tt |
| HH | hh | - |
| TTH | h | tth |
| M wins | hhh | $?$ |
| R wins | $?$ | tthh |

By claiming that these states summarize the game I am tacitly assuming that the coin has no "memory", in the sense that the conditional probability of a head given any particular past sequence of heads and tails is $1 / 2$ (for a fair coin). The past history leading to a particular state does not matter; the future evolution of the game depends only on what remains for each player to achieve his desired pattern.

The game is nicely summarized by a diagram with states represented by little boxes joined by arrows that indicate the probabilities of transition from one state to another. Only transitions with a nonzero probability are drawn. In this problem each nonzero probability equals $1 / 2$. The solid arrows correspond to transitions resulting from a head, the dotted arrows to a tail.

For example, the arrows leading from $S$ to $H$ to $H H$ to $M$ wins correspond to heads; the game would progress in exactly that way if the first three tosses gave hhh. Similarly the arrows from $[S$ to $T$ to $T T$ correspond to tails.

The arrow looping from TT back into itself corresponds to the situation where, after ...tt, both players progress no further until the next head. Once the game progresses down the arrow T] to TT the step into TTH becomes inevitable. Indeed, for the purpose of calculating the probability that M wins, we could replace the side branch by:

The new arrow from T to TTH would correspond to a sequence of tails followed by a head. With the state TT removed, the diagram would become almost symmetric with respect to M and R . The arrow from HH back to T would show that R actually has an advantage: the first h in the tthh pattern presents no obstacle to him.

Once we have the diagram we can forget about the underlying game. The problem becomes one of following the path of a mouse that moves between the states according to the transition probabilities on the arrows. The original game has $S$ as its starting state, but it is just as easy to solve the problem for a particle starting from any of the states. The method that I will present actually solves the problems for all possible starting states by setting up equations that relate the solutions to each other. Define probabilities for the mouse:

$$
\begin{aligned}
& P_{S}=\mathbb{P}\{\text { reach M wins } \mid \text { start at } \mathrm{S}\} \\
& P_{T}=\mathbb{P}\{\text { reach M wins } \mid \text { start at T }\}
\end{aligned}
$$

and so on. I'll still refer to the solid arrows as "heads", just to distinguish between the two arrows leading out of a state, even though the coin tossing interpretation has now become irrelevant.

Calculate the probability of reaching $M$ wins, under each of the different starting circumstances, by breaking according to the result of the first move,
and then conditioning.

$$
\begin{aligned}
P_{S}= & \mathbb{P}\{\text { reach M wins, heads } \mid \text { start at } S\}\} \\
& +\mathbb{P}\{\text { reach M wins, tails } \mid \text { start at } S\} \\
= & \mathbb{P}\{\text { heads } \mid \text { start at }[ \}\} \mathbb{P}\{\text { reach } M \text { wins } \mid \text { start at } S, \text { heads }\} \\
& +\mathbb{P}\{\text { tails } \mid \text { start at }[ \}\} \mathbb{P}\{\text { reach M wins } \mid \text { start at } S, \text { tails }\} .
\end{aligned}
$$

The assumed lack of memory for the fair coin reduces the last expression to $\frac{1}{2} P_{H}+\frac{1}{2} P_{T}$. Notice how the conditioning information "start at $S$, heads" has been replaced by "start at $H$ ", and so on. We have our first equation:

$$
P_{S}=\frac{1}{2} P_{H}+\frac{1}{2} P_{T}
$$

Similar splitting and conditioning arguments for each of the other starting states give

$$
\begin{aligned}
P_{H} & =\frac{1}{2} P_{T}+\frac{1}{2} P_{H H} \\
P_{H H} & =\frac{1}{2}+\frac{1}{2} P_{T} \\
P_{T} & =\frac{1}{2} P_{H}+\frac{1}{2} P_{T T} \\
P_{T T} & =\frac{1}{2} P_{T T}+\frac{1}{2} P_{T T H} \\
P_{T T H} & =\frac{1}{2} P_{T}+0 .
\end{aligned}
$$

We could use the fourth equation to substitute for $P_{T T}$, leaving

$$
P_{T}=\frac{1}{2} P_{H}+\frac{1}{2} P_{T T H} .
$$

This simple elimination of the $P_{T T}$ contribution corresponds to the excision of the TT state from the diagram. If we hadn't noticed the possibility for excision the algebra would have effectively done it for us. The six splitting/conditioning arguments give six linear equations in six unknowns. If you solve them you should get $P_{S}=5 / 12, P_{H}=1 / 2, P_{T}=1 / 3, P_{H H}=2 / 3$, and $P_{T T H}=1 / 6$. For the original problem, M has probability $5 / 12$ of winning.

There is a more systematic way to carry out the analysis in the last problem without drawing the diagram. The transition probabilities can be installed into an 8 by 8 matrix whose rows and columns are labeled by the
states:

If we similarly define a column vector,

$$
\pi=\left(P_{S}, P_{H}, P_{T}, P_{H H}, P_{T T}, P_{T T H}, P_{\mathrm{M} \text { wins }}, P_{\mathrm{R} \text { wins }}\right)^{\prime},
$$

then the equations that we needed to solve could be written as

$$
P \pi=\pi,
$$

with the boundary conditions $P_{\mathrm{M} \text { wins }}=1$ and $P_{\mathrm{R} \text { wins }}=0$.
Remark. Write $e_{M}^{\prime}$ and $e_{R}^{\prime}$ for the last two rows of $P$ and $Q$ for the $6 \times 8$ matrix made up of the first 6 rows of $I-P$. Then $\pi$ is the unique solution to the equation

$$
\left[\begin{array}{c}
Q \\
e_{M}^{\prime} \\
e_{R}^{\prime}
\end{array}\right] \pi=e_{M}
$$

The matrix $P$ is called the transition matrix. The element in row i and column j gives the probability of a transition from state i to state j. For example, the third row, which is labeled T, gives transition probabilities from state T . If we multiply $P$ by itself we get the matrix $P^{2}$, which gives the "two-step" transition probabilities. For example, the element of $P^{2}$ in row T and column TTH is given by

$$
\sum_{j} P_{T, j} P_{j, T T H}=\sum_{j} \mathbb{P}\{\text { step to } \mathrm{j} \mid \text { start at } \boxed{T}\} \mathbb{P}\{\text { step to } \boxed{\mathrm{TTH}} \mid \text { start at } \mathrm{j}\} .
$$

Here $j$ runs over all states, but only $j=\mathrm{H}$ and $j=\mathrm{TT}$ contribute nonzero terms. Substituting

$$
\mathbb{P}\{\text { reach TTH in two steps } \mid \text { start at } \mathbb{T} \text {, step to }\}
$$

for the second factor in the sum, we get the splitting/conditioning decomposition for

$$
\mathbb{P}\{\text { reach TTH in two steps } \mid \text { start at T }\} \text {, }
$$

a two-step transition possibility.
Remark. What do the elements of the matrix $P^{n}$ represent? What happens to this matrix as $n$ tends to infinity? If you are interested in computation, look at the file HHH.TTHH.R, or try similar calculations with Matlab or Mathematica.

The name Markov chain is given to any process representable as the movement of a mouse (or a particle) between states (boxes) according to transition probabilities attached to arrows connecting the various states. The sum of the probabilities for arrows leaving a state should add to one. All the past history except for identification of the current state is regarded as irrelevant to the next transition; given the current state, the past is conditionally independent of the future.

## Example 5.

Suppose a coin has probability $p$ of landing heads on any particular toss, independent of outcomes of other tosses. In a sequence of such tosses, what is the probability that the first head appears on the kth toss (for $k=1,2, \ldots$ )?

Write $H_{i}$ for the event \{head on the ith toss\}. Then, for a fixed $k$ (an integer greater than or equal to 1 ),

$$
\begin{aligned}
& \mathbb{P}\{\text { first head on kth toss }\} \\
& \quad=\mathbb{P}\left(H_{1}^{c} H_{2}^{c} \ldots H_{k-1}^{c} H_{k}\right) \\
& \quad=\mathbb{P}\left(H_{1}^{c}\right) \mathbb{P}\left(H_{2}^{c} \ldots H_{k-1}^{c} H_{k} \mid H_{1}^{c}\right) \quad \text { by rule } \mathrm{P} 5 .
\end{aligned}
$$

By the independence assumption, the conditioning information is irrelevant. Also $\mathbb{P} H_{1}^{c}=1-p$ because $\mathbb{P} H_{1}^{c}+\mathbb{P} H_{1}=1$. Why? Thus

$$
\mathbb{P}\{\text { first head on kth toss }\}=(1-p) \mathbb{P}\left(H_{2}^{c} \ldots H_{k-1}^{c} H_{k}\right) .
$$

Similar conditioning arguments let us strip off each of the outcomes for tosses 2 to $k-1$, leaving

$$
\mathbb{P}\{\text { first head on kth toss }\}=(1-p)^{k-1} p \quad \text { for } k=1,2, \ldots
$$

## Example 6.

(The Three-Cornered Duel-also borrowed from Mosteller, 1987) A, B, and C are to fight a three-cornered pistol duel. All know that A's chance of hitting his target is 0.3 , C's is 0.5 , and B never misses. They are to fire at their choice of target in succession in the order A, B, C, cyclically (but a hit man loses further turns and is no longer shot at) until only one man is left unhit. What should A's strategy be?

What could A do? If he shoots at C and hits him, then he receives a bullet between the eyes from B on the next shot. Not a good strategy:

$$
\mathbb{P}(\text { A survives } \mid \text { he kills } C \text { first })=0
$$

If he shoots at C and misses then B naturally would pick off his more dangerous oppenent, C, leaving A one shot before B finishes him off too. That single shot from A at B would have to succeed:

$$
\mathbb{P}(\text { A survives } \mid \text { he misses first shot })=0.3 \text {. }
$$

If A shoots first at B and misses the result is the same. What if A shoots at B first and succeeds? Then A and C would trade shots until one of them was hit, with C taking the first shot. We could solve this part of the problem by setting up a Markov chain diagram, or we could argue as follows: For A to survive, the fight would have to continue,

$$
\{\mathrm{C} \text { misses, A hits }\}
$$

or

$$
\{\mathrm{C} \text { misses, A misses, C misses, A hits }\}
$$

or

$$
\{\mathrm{C} \text { misses, (A misses, } \mathrm{C} \text { misses) twice, A hits }\}
$$

and so on. The general piece in the decomposition consists of some number of repetitions of (A misses, C misses) sandwiched between the initial "C misses" and the final "A hits." The repetitions are like coin tosses with probability $(1-0.3)(1-0.5)=.35$ for the double miss. Independence between successive shots (or should it be conditional independence, given
the choice of target?) allows us to multiply together probabilities to get

$$
\begin{aligned}
& \mathbb{P}(\mathrm{A} \text { survives } \mid \text { he first shoots B) } \\
& \quad=\sum_{k=0}^{\infty} \mathbb{P}\{\mathrm{C} \text { misses, (A misses, C misses) } \mathrm{k} \text { times, A hits }\} \\
& \\
& =\sum_{k=0}^{\infty}(.5)(.35)^{k}(.3) \\
& \quad=.15 /(1-0.35) \quad \text { by the rule of sum of geometric series } \\
& \\
& \approx .23
\end{aligned}
$$

In summary:

$$
\begin{aligned}
& \mathbb{P}(\text { A survives } \mid \text { he kills } C \text { first })=0 \\
& \mathbb{P}(\text { A survives } \mid \text { he kills } B \text { first }) \approx .23 \\
& \mathbb{P}(\text { A survives } \mid \text { he misses with first shot })=.3
\end{aligned}
$$

Somehow A should try to miss with his first shot. Is that allowed?

## Chapter 2

## Expectations

Recall from Chapter 1 that a random variable is just a function that attaches a number to each item in the sample space. Less formally, a random variable corresponds to a numerical quantity whose value is determined by some chance mechanism.

Just as events have (conditional) probabilities attached to them, with possible interpretation as a long-run frequency, so too do random variables have a number interpretable as a long-run average attached to them. Given a particular piece of information, the symbol

$$
\mathbb{E}(X \mid \text { information })
$$

denotes the (conditional) expected value or (conditional) expectation of the random variable $X$ (given that information). When the information is taken as understood, the expected value is abbreviated to $\mathbb{E} X$.

Expected values are not restricted to lie in the range from zero to one. For example, if the info forces a random variable $X$ to always take values larger than 16 then $\mathbb{E}(X \mid$ info $)$ will be larger than 16 .

As with conditional probabilities, there are convenient abbreviations when the conditioning information includes something like \{event $F$ has occurred\}:

$$
\begin{array}{l|l}
\mathbb{E}(X & \text { information and " } F \text { has occurred" }) \\
\mathbb{E}(X \mid \text { information, } F)
\end{array}
$$

Unlike many authors, I will take the expected value as a primitive concept, not one to be derived from other concepts. All of the methods that those authors use to define expected values will be derived from a small number of basic rules. I will provide an interpretation for just one of the rules, using long-run averages of values generated by independent repetitions of random experiments. You should provide analogous interpretations for the other rules.

Remark. See the Appendix to this Chapter for another interpretation, which does not depend on a preliminary concept of independent repetitions of an experiment. The expected value $\mathbb{E} X$ can be interpreted as a"fair price" to pay up-front, in exchange for a random return $X$ later-something like an insurance premium.

## Rules for (conditional) expectations.

Let $X$ and $Y$ be random variables, $c$ and $d$ be constants, and $F_{1}, F_{2}, \ldots$ be events. Then:
$(\mathrm{E} 1) \mathbb{E}(c X+d Y \mid$ info $)=c \mathbb{E}(X \mid$ info $)+d \mathbb{E}(Y \mid$ info $) ;$
(E2) if X can only take the constant value $c$ under the given "info" then $\mathbb{E}(X \mid$ info $)=c ;$
(E3) if the given "info" forces $X \leq Y$ then $\mathbb{E}(X \mid$ info $) \leq \mathbb{E}(Y \mid$ info $)$;
(E4) if the events $F_{1}, F_{2}, \ldots$ are disjoint and have union equal to the whole sample space then

$$
\mathbb{E}(X \mid \text { info })=\sum_{i} \mathbb{E}\left(X \mid F_{i}, \text { info }\right) \mathbb{P}\left(F_{i} \mid \text { info }\right)
$$

Rule (E4) combines the power of both rules (P4) and (P5) for conditional probabilities. Here is the frequency interpretation for the case of two disjoint events $F_{1}$ and $F_{2}$ with union $S$ : Repeat the experiment a very large number $(n)$ of times, noting for each repetition the value taken by $X$ and which of $F_{1}$ or $F_{2}$ occurs.

|  | 1 | 2 | 3 | 4 | $\ldots$ |  |  | $n-1$ | $n$ | total |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $F_{1}$ occurs | $\checkmark$ | $\checkmark$ |  | $\checkmark$ | $\ldots$ |  |  |  | $\checkmark$ | $\checkmark$ |
| $F_{2}$ occurs |  |  | $\checkmark$ |  | $\ldots$ | $\checkmark$ | $\checkmark$ | $\checkmark$ |  |  |
| $X$ | $x_{1}$ | $x_{2}$ | $x_{3}$ | $x_{4}$ | $\ldots$ |  |  |  | $x_{n-1}$ | $x_{n}$ |

By the frequency interpretation of probabilities, $\mathbb{P}\left(F_{1} \mid\right.$ info $) \approx n_{1} / n$ and $\mathbb{P}\left(F_{2} \mid\right.$ info $) \approx n_{2} / n$. Those trials where $F_{1}$ occurs correspond to conditioning on $F_{1}$ :

$$
\mathbb{E}\left(X \mid F_{1}, \text { info }\right) \approx \frac{1}{n_{1}} \sum_{F_{1} \text { occurs }} x_{i}
$$

Similarly,

$$
\mathbb{E}\left(X \mid F_{2}, \text { info }\right) \approx \frac{1}{n_{2}} \sum_{F_{2} \text { occurs }} x_{i}
$$

Thus

$$
\begin{aligned}
& \mathbb{E}\left(X \mid F_{1}, \text { info }\right) \mathbb{P}\left(F_{1} \mid \text { info }\right)+\mathbb{E}\left(X \mid F_{2}, \text { info }\right) \mathbb{P}\left(F_{2} \mid \text { info }\right) \\
& \approx\left(\frac{1}{n_{1}} \sum_{F_{1} \text { occurs }} x_{i}\right)\left(\frac{n_{1}}{n}\right)+\left(\frac{1}{n_{2}} \sum_{F_{2} \text { occurs }} x_{i}\right)\left(\frac{n_{2}}{n}\right) \\
& =\frac{1}{n} \sum_{i=1}^{n} x_{i} \\
& \approx \mathbb{E}(X \mid \text { info }) .
\end{aligned}
$$

As $n$ gets larger and larger all approximations are supposed to get better and better, and so on.

Modulo some fine print regarding convergence of infinite series, rule (E1) extends to sums of infinite sequences of random variables,

$$
\begin{equation*}
\mathbb{E}\left(X_{1}+X_{2}+\ldots\right)=\mathbb{E}\left(X_{1}\right)+\mathbb{E}\left(X_{2}\right)+\ldots \tag{E1}
\end{equation*}
$$

(For mathematical purists: the asserted equality holds if $\sum_{i} \mathbb{E}\left|X_{i}\right|<\infty$.)
Remark. The rules for conditional expectations actually include all the rules for conditional probabilities as special cases. This delightfully convenient fact can be established by systematic use of particularly simple random variables. For each event $A$ the indicator function of $A$ is defined by

$$
\mathbb{I}_{A}= \begin{cases}1 & \text { if the event } A \text { occurs, } \\ 0 & \text { if the event } A^{c} \text { occurs. }\end{cases}
$$

Each $\mathbb{I}_{A}$ is a random variable.
Rule (E4) with $F_{1}=A$ and $F_{2}=A^{c}$ gives

$$
\begin{aligned}
\mathbb{E}\left(\mathbb{I}_{A} \mid \text { info }\right)= & \mathbb{E}\left(\mathbb{I}_{A} \mid A, \text { info }\right) \mathbb{P}(A \mid \text { info })+ \\
& +\mathbb{E}\left(\mathbb{I}_{A} \mid A^{c}, \text { info }\right) \mathbb{P}\left(A^{c} \mid \text { info }\right) \\
= & \left.\times \mathbb{P}(A \mid \text { info })+0 \times \mathbb{P}\left(A^{c} \mid \text { info }\right) \quad \text { by (E2 }\right) .
\end{aligned}
$$

That is, $\mathbb{E}\left(\mathbb{I}_{A} \mid\right.$ info $)=\mathbb{P}(A \mid$ info $)$.
If an event $A$ is a disjoint union of events $A_{1}, A_{2}, \ldots$ then $\mathbb{I}_{A}=\mathbb{I}_{A_{1}}+\mathbb{I}_{A_{2}}+\ldots$ (Why?) Taking expectations then invoking the version of (E1) for infinite sums we get rule (P4).

As an exercise, you might try to derive the other probability rules, but don't spend much time on the task or worry about it too much. Just keep buried somewhere in the back of your mind the idea that you can do more with expectations than with probabilities alone.

You will find it useful to remember that $\mathbb{E}\left(\mathbb{I}_{A} \mid\right.$ info $)=\mathbb{P}(A \mid$ info $)$, a result that is easy to recall from the fact that the long-run frequency of occurrence of an event, over many repetitions, is just the long-run average of its indicator function.

Rules (E2) and (E4) can be used to calculate expectations from probabilities for random variables that take values in "discrete" set. Consider the case of a random variable $Y$ expressible as a function $g(X)$ of another random variable, $X$, which takes on only a discrete set of values $c_{1}, c_{2}, \ldots$. Let $F_{i}$ be the subset of $S$ on which $X=c_{i}$, that is, $F_{i}=\left\{X=c_{i}\right\}$. Then by E2,

$$
\mathbb{E}\left(Y \mid F_{i}, \text { info }\right)=g\left(c_{i}\right),
$$

and by E5,

$$
\mathbb{E}(Y \mid \text { info })=\sum_{i} g\left(c_{i}\right) \mathbb{P}\left(F_{i} \mid \text { info }\right) .
$$

More succinctly,

$$
\begin{equation*}
\mathbb{E}(g(X) \mid \text { info })=\sum_{i} g\left(c_{i}\right) \mathbb{P}\left(X=c_{i} \mid \text { info }\right) . \tag{E5}
\end{equation*}
$$

In particular,

$$
\begin{equation*}
\mathbb{E}(X \mid \text { info })=\sum_{i} c_{i} \mathbb{P}\left(X=c_{i} \mid \text { info }\right) \tag{E5}
\end{equation*}
$$

Both (E5) and (E5)' apply to random variables that take values in the "discrete set" $\left\{c_{1}, c_{2}, \ldots\right\}$.

Remark. For random variables that take a continuous range of values an approximation argument (see Chapter 7 ) will provide us with an analog of (E5) with the sum replaced by an integral.

You will find it helpful to remember expectations for a few standard mechanisms, such as coin tossing, rather than have to rederive them repeatedly.
$<1>\quad$ Example. Expected value for the geometric $(p)$ distribution is $1 / p$.
The calculation of an expectation is often a good way to get a rough feel for the behaviour of a random process, but it doesn't tell the whole story.

Example. Expected number of tosses to get thh with fair coin is 16 .
By similar arguments (see HW2), you can show that the expected number of tosses needed to get hhh, without competition, is 14 . Doesn't that seem strange? On average it takes longer to reach thh than hhh, but also on average the pattern tthh appears first.

Remark. You should also be able to show that the expected number of tosses for the completion of the game with competition between hhh and tthh is $91 / 3$. Notice that the expected value for the game with competition is smaller than the minimum of the expected values for the two games. Why must it be smaller?

Probabilists study standard mechanisms, and establish basic results for them, partly in the hope that they will recognize those same mechanisms buried in other problems. In that way, unnecessary calculation can be avoided, making it easier to solve more complex problems. It can, however, take some work to find the hidden mechanism.
$<3>$ Example. [Coupon collector problem] In order to encourage consumers to buy many packets of cereal, a manufacurer includes a Famous Probabilist card in each packet. There are 10 different types of card: Chung, Feller, Lévy, Kolmogorov, ..., Doob. Suppose that I am seized by the desire to own at least one card of each type. What is the expected number of packets that I need to buy in order to achieve my goal?

For the coupon collectors problem I assumed large numbers of cards of each type, in order to justify the analogy with coin tossing. Without that assumption the depletion of cards from the population would have a noticeable effect on the proportions of each type remaining after each purchase. The next example illustrates the effects of sampling from a finite population without replacement, when the population size is not assumed very large.

The example will also provides an illustration of the method of indicators, whereby a random variable is expressed as a sum of indicator variables $\mathbb{I}_{A_{1}}+\mathbb{I}_{A_{2}}+\ldots$, in order to reduce calculation of an expected value to separate calculation of probabilities $\mathbb{P} A_{1}, \mathbb{P} A_{2}, \ldots$ via the formula

$$
\begin{aligned}
& \mathbb{E}\left(\mathbb{I}_{A_{1}}+\mathbb{I}_{A_{2}}+\ldots \mid \text { info }\right) \\
& \quad=\mathbb{E}\left(\mathbb{I}_{A_{1}} \mid \text { info }\right)+\mathbb{E}\left(\mathbb{I}_{A_{2}} \mid \text { info }\right)+\ldots \\
& \quad=\mathbb{P}\left(A_{1} \mid \text { info }\right)+\mathbb{P}\left(A_{2} \mid \text { info }\right)+\mathbb{P}\left(A_{2} \mid \text { info }\right)+\ldots
\end{aligned}
$$

<4>
Example. Suppose an urn contains r red balls and b black balls, all identical except for color. Suppose you remove one ball at a time, without replacement, at each step selecting at random from the urn: if $k$ balls remain then each has probability $1 / k$ of being chosen.Show that the expected number of red balls removed before the firstblack ball equals $r /(b+1)$.

Compare the solution $r /(b+1)$ with the result for sampling with replacement, where the number of draws required to get the first black would have a geometric $(b /(r+b))$ distribution. With replacement, the expected number of reds removed before the first black would be

$$
(b /(r+b))^{-1}-1=r / b .
$$

Replacement of balls after each draw increases the expected value slightly. Does that make sense?

The conditioning property (E5) can be used in a subtle way to solve the classical gambler's ruin problem. The method of solution invented by Abraham de Moivre, over two hundred years ago, has grown into one of the main technical tools of modern probability.
$<5>\quad$ Example. Suppose two players, Alf and Betamax, bet on the tosses of a fair coin: for a head, Alf pays Betamax one dollar; for a tail, Betamax pays Alf one dollar. The stop playing when one player runs out of money. If Alf starts with $\alpha$ dollar bills, and Betamax starts with $\beta$ dollars bills (both $\alpha$ and $\beta$ whole numbers), what is the probability that Alf ends up with all the money?

De Moivre's method also works with biased coins, if we count profits in a different way -an even more elegant application of conditional expectations. The next Example provides the details. You could safely skip it if you understand the tricky idea behind Example $<5>$.
$<6>$ Example. Same problem as in Example $<5>$, except that the coin they toss has probability $p \neq 1 / 2$ of landing heads. (Could be skipped.)

You could also safely skip the final Example. It contains a discussion of a tricky little problem, that can be solved by conditioning or by an elegant symmetry argument.
$<7>\quad$ Example. Big pills, little pills. (Tricky. Should be skipped.)

## Things to remember.

- Expectations (and conditional expectations) are linear (E1), increasing (E3) functions of random variables, which can be calculated as weighted averages of conditional expectations,

$$
\mathbb{E}(X \mid \text { info })=\sum_{i} \mathbb{E}\left(X \mid F_{i}, \text { info }\right) \mathbb{P}\left(F_{i} \mid \text { info }\right)
$$

where the disjoint events $F_{1}, F_{2}, \ldots$ cover all possibilities (the weights sum to one).

- The indicator function of an event $A$ is the random variable defined by

$$
\mathbb{I}_{A}= \begin{cases}1 & \text { if the event } A \text { occurs, } \\ 0 & \text { if the event } A^{c} \text { occurs. }\end{cases}
$$

The expected value of an indicator variable, $\mathbb{E}\left(\mathbb{I}_{A} \mid\right.$ info $)$, is the same as the probability of the corresponding event, $\mathbb{P}(A \mid$ info $)$.

- As a consequence of the rules,

$$
\mathbb{E}(g(X) \mid \text { info })=\sum_{i} g\left(c_{i}\right) \mathbb{P}\left(X=c_{i} \mid \text { info }\right),
$$

if $X$ can take only values $c_{1}, c_{2}, \ldots$.

## Example 1.

For independent coin tossing, what is the expected value of $X$, the number of tosses to get the first head?

Suppose the coin has probability $p>0$ of landing heads. (So we are actually calculating the expected value for the geometric $(p)$ distribution.) I will present two methods.

## Method A: a Markov argument without the picture.

Condition on whether the first toss lands heads $\left(H_{1}\right)$ or tails $\left(T_{1}\right)$.

$$
\begin{aligned}
\mathbb{E} X & =\mathbb{E}\left(X \mid H_{1}\right) \mathbb{P} H_{1}+\mathbb{E}\left(X \mid T_{1}\right) \mathbb{P} T_{1} \\
& =(1) p+(1+\mathbb{E} X)(1-p) .
\end{aligned}
$$

The reasoning behind the equality

$$
\mathbb{E}\left(X \mid T_{1}\right)=1+\mathbb{E} X
$$

is: After a tail we are back where we started, still counting the number of tosses until a head, except that the first tail must be included in that count. Solving the equation for $\mathbb{E} X$ we get

$$
\mathbb{E} X=1 / p
$$

Does this answer seem reasonable? (Is it always at least 1? Does it decrease as $p$ increases? What happens as $p$ tends to zero or one?)

## Method B.

By the formula (E5),

$$
\mathbb{E} X=\sum_{k=1}^{\infty} k(1-p)^{k-1} p
$$

There are several cute ways to sum this series. Here is my favorite. Write $q$ for $1-p$. Write the kth summand as a a column of $k$ terms $p q^{k-1}$, then sum by rows:

$$
\begin{aligned}
\mathbb{E} X=p+p q & +p q^{2}+p q^{3}+\ldots \\
+p q & +p q^{2}+p q^{3}+\ldots \\
+p q^{2} & +p q^{3}+\ldots \\
& +p q^{3}+\ldots
\end{aligned}
$$

Each row is a geometric series.

$$
\begin{aligned}
\mathbb{E} X & =p /(1-q)+p q /(1-q)+p q^{2} /(1-q)+\ldots \\
& =1+q+q^{2}+\ldots \\
& =1 /(1-q) \\
& =1 / p,
\end{aligned}
$$

same as before.

## Example 2.

The "HHH versus TTHH" Example in Chapter 1 solved the following problem:

Imagine that I have a fair coin, which I toss repeatedly. Two players, M and R , observe the sequence of tosses, each waiting for a particular pattern on consecutive tosses: M waits for hhh, and R waits for tthh. The one whose pattern appears first is the winner. What is the probability that M wins?

The answer-that M has probability $5 / 12$ of winning-is slightly surprising, because, at first sight, a pattern of four appears harder to achieve than a pattern of three.

A calculation of expected values will add to the puzzlement. As you will see, if the game is continued until each player sees his pattern, it takes tthh longer (on average) to appear than it takes hhh to appear. However, when the two patterns are competing, the tthh pattern is more likely to appear first. How can that be?

For the moment forget about the competing hhh pattern: calculate the expected number of tosses needed before the pattern tthh is obtained with four successive tosses. That is, if we let $X$ denote the number of tosses required then the problem asks for the expected value $\mathbb{E} X$.

The Markov chain diagram keeps track of the progress from the starting state (labelled S) to the state TTHH where the pattern is achieved. Each arrow in the diagram corresponds to a transition between states with probability $1 / 2$. The corresponding transition matrix is:

Once again it is easier to solve not just the original problem, but a set of problems, one for each starting state. Let

$$
\begin{aligned}
\mathcal{E}_{S} & =\mathbb{E}(X \mid \text { start at } \mathrm{S}) \\
\mathcal{E}_{H} & =\mathbb{E}(X \mid \text { start at } \mathrm{H}) \\
\vdots &
\end{aligned}
$$

Then the original problem is asking for the value of $\varepsilon_{S}$.
Condition on the outcome of the first toss, writing $\mathcal{H}$ for the event \{first toss lands heads\} and $\mathcal{T}$ for the event \{first toss lands tails\}. From rule E4 for expectations,

$$
\begin{aligned}
\mathcal{E}_{S}=\mathbb{E} & (X \mid \text { start at } \mathrm{S}, \mathcal{T}) \mathbb{P}(\mathcal{T} \mid \text { start at } \mathrm{S}) \\
& +\mathbb{E}(X \mid \text { start at } \mathrm{S}, \mathcal{H}) \mathbb{P}(\mathcal{H} \mid \text { start at } \mathrm{S})
\end{aligned}
$$

Both the conditional probabilities equal $1 / 2$ ("fair coin"; probability does not depend on the state). For the first of the conditional expectations, count 1 for the first toss, then recognize that the remaining tosses are just those needed to reach TTHH starting from the state $T$ :

$$
\mathbb{E}(X \mid \text { start at } \mathrm{S}, \mathcal{T})=1+\mathbb{E}(X \mid \text { start at } \mathrm{T})
$$

Don't forget to count the first toss. An analogous argument leads to an analogous expression for the second conditional expectation. Substitution into the expression for $\mathcal{E}_{S}$ then gives

$$
\mathcal{E}_{S}=\frac{1}{2}\left(1+\varepsilon_{T}\right)+\frac{1}{2}\left(1+\varepsilon_{S}\right)
$$

Similarly,

$$
\begin{aligned}
\varepsilon_{T} & =\frac{1}{2}\left(1+\mathcal{E}_{T T}\right)+\frac{1}{2}\left(1+\varepsilon_{S}\right) \\
\mathcal{E}_{T T} & =\frac{1}{2}\left(1+\varepsilon_{T T}\right)+\frac{1}{2}\left(1+\varepsilon_{T T H}\right) \\
\mathcal{E}_{T T H} & =\frac{1}{2}(1+0)+\frac{1}{2}\left(1+\varepsilon_{T}\right)
\end{aligned}
$$

What does the zero in the last equation represent?
The four linear equations in four unknowns have the solution $\mathcal{E}_{S}=16$, $\mathcal{E}_{T}=14, \mathcal{E}_{T T}=10, \mathcal{E}_{T T H}=8$. Thus, the solution to the original problem is that the expected number of tosses to achieve the tthh pattern is 16 .

## Example 3.

In order to encourage consumers to buy many packets of cereal, a manufacurer includes a Famous Probabilist card in each packet. There are 10 different types of card: Chung, Feller, Lévy, Kolmogorov, ..., Doob. Suppose that I am seized by the desire to own at least one card of each type. What is the expected number of packets that I need to buy in order to achieve my goal?

Assume that the manufacturer has produced enormous numbers of cards, the same number for each type. (If you have ever tried to collect objects of this type, you might doubt the assumption about equal numbers. But, without it, the problem becomes exceedingly difficult.) The assumption ensures, to a good approximation, that the cards in different packets are independent, with probability $1 / 10$ for a Chung, probability $1 / 10$ for a Feller, and so on.

The high points in my life occur at random "times" $T_{1}, T_{1}+T_{2}, \ldots$, $T_{1}+T_{2}+\cdots+T_{10}$, when I add a new type of card to my collection: After one card (that is, $T_{1}=1$ ) I have my first type; after another $T_{2}$ cards I will get something different from the first card; after another $T_{3}$ cards I will get a third type; and so on.

The question asks for $\mathbb{E}\left(T_{1}+T_{2}+\cdots+T_{10}\right)$, which rule E 1 (applied repeatedly) reexpresses as $\mathbb{E} T_{1}+\mathbb{E} T_{2}+\cdots+\mathbb{E} T_{10}$.

The calculation for $\mathbb{E} T_{1}$ is trivial because $T_{1}$ must equal 1: we get $\mathbb{E} T_{1}=1$ by rule (E2). Consider the mechanism controlling $T_{2}$. For concreteness suppose the first card was a Doob. Each packet after the first is like a coin toss with probability $9 / 10$ of getting a head ( $=$ a nonDoob), with $T_{2}$ like the number of tosses needed to get the first head. Thus

$$
T_{2} \text { has a geometric }(9 / 10) \text { distribution. }
$$

Deduce from Example $<1>$ that $\mathbb{E} T_{2}=10 / 9$, a value slightly larger than 1 .
Now consider the mechanism controlling $T_{3}$. Condition on everything that was observed up to time $T_{1}+T_{2}$. Under the assumption of equal abundance and enormous numbers of cards, most of this conditioning information is acually irrelevent; the mechanism controlling $T_{3}$ is independent of the past information. (Hard question: Why would the $T_{2}$ and $T_{3}$ mechanisms not be independent if the cards were not equally abundant?) So what is that $T_{3}$ mechanism? I am waiting for any one of the 8 types I have not yet collected. It is like coin tossing with probability $8 / 10$ of heads:
$T_{3}$ has geometric (8/10) distribution,
and thus $\mathbb{E} T_{3}=10 / 8$.
Remark. More precisely, $T_{3}$ is independent of $T_{2}$ with conditional probability distribution geometric ( $8 / 10$ ). That is, with $p=8 / 10$,

$$
\mathbb{P}\left\{T_{3}=k \mid T_{2}=\ell\right\}=(1-p)^{k-1} p \quad \text { for } k=1,2, \ldots
$$

for every possible $\ell$.

And so on, leading to

$$
\mathbb{E} T_{1}+\mathbb{E} T_{2}+\cdots+\mathbb{E} T_{10}=1+10 / 9+10 / 8+\ldots+10 / 1 \approx 29.3
$$

I should expect to buy about 29.3 packets to collect all ten cards.
Note: The independence between packets was not needed to justify the appeal to rule (E1), to break the expected value of the sum into a sum of expected values. It did allow me to recognize the various geometric distributions without having to sort through possible effects of large $T_{2}$ on the behavior of $T_{3}$, and so on.

You might appreciate better the role of independence if you try to solve a similar (but much harder) problem with just two sorts of card, not in equal proportions.

## Example 4.

Suppose an urn contains red balls and b black balls, all identical except for color. Suppose you remove one ball at a time, without replacement, at each step selecting at random from the urn: if $k$ balls remain then each has probability $1 / k$ of being chosen.Show that the expected number of red balls removed before the firstblack ball equals $r /(b+1)$.
The problem might at first appear to require nothing more than a simple application of rule (E5)' for expectations. We shall see. Let $T$ be the number of reds removed before the first black. Find the distribution of $T$, then appeal to E5 ${ }^{\prime}$ to get

$$
\mathbb{E} T=\sum_{k} k \mathbb{P}\{T=k\}
$$

Sounds easy enough. We have only to calculate the probabilities $\mathbb{P}\{T=k\}$.
Define $R_{i}=\{i$ th ball red $\}$ and $B_{i}=\{i$ th ball black $\}$. The possible values for $T$ are $0,1, \ldots, r$. For $k$ in this range,

$$
\begin{aligned}
\mathbb{P}\{T=k\} & =\mathbb{P}\{\text { first } \mathrm{k} \text { balls red, }(\mathrm{k}+1) \mathrm{st} \text { ball is black }\} \\
& =\mathbb{P}\left(R_{1} R_{2} \ldots R_{k} B_{k+1}\right) \\
& =\left(\mathbb{P} R_{1}\right) \mathbb{P}\left(R_{2} \mid R_{1}\right) \mathbb{P}\left(R_{3} \mid R_{1} R_{2}\right) \ldots \mathbb{P}\left(B_{k+1} \mid R_{1} \ldots R_{k}\right) \\
& =\frac{r}{r+b} \cdot \frac{r-1}{r+b-1} \ldots \frac{b}{r+b-k} .
\end{aligned}
$$

The dependence on $k$ is fearsome. I wouldn't like to try multiplying by k and summing. If you are into pain you might try to continue this line of argument. Good luck.

There is a much easier way to calculate the expectation, by breaking $T$ into a sum of much simpler random variables for which (E5)' is trivial to apply. This approach is sometimes called the method of indicators.

Suppose the red balls are labelled $1, \ldots, r$. Let $T_{i}$ equal 1 if red ball number $i$ is sampled before the first black ball, zero otherwise. That is, $T_{i}$ is the indicator for the event
\{red ball number $i$ is removed before any of the black balls\}.
(Be careful here. The black balls are not thought of as numbered. The first black ball is not a ball bearing the number 1 ; it might be any of the $b$ black balls in the urn.) Then $T=T_{1}+\cdots+T_{r}$. By symmetry-it is assumed that the numbers have no influence on the order in which red balls are selected-each $T_{i}$ has the same expectation. Thus

$$
\mathbb{E} T=\mathbb{E} T_{1}+\cdots+\mathbb{E} T_{r}=r \mathbb{E} T_{1} .
$$

For the calculation of $\mathbb{E} T_{1}$ we can ignore most of the red balls. The event $\left\{T_{1}=1\right\}$ occurs if and only if red ball number 1 is drawn before all $b$ of the black balls. By symmetry, the event has probability $1 /(b+1)$. (If $b+1$ objects are arranged in random order, each object has probability $1 /(1+b)$ of appearing first in the order.)

Remark. If you are not convinced by the appeal to symmetry, you might find it helpful to consider a thought experiment where all $r+b$ balls are numbered and they are removed at random from the urn. That is, treat all the balls as distinguishable and sample until the urn is empty. (You might find it easier to follow the argument in a particular case, such as all $120=5$ ! orderings for five distinguishable balls, 2 red and 3 black.) The sample space consists of all permutations of the numbers 1 to $r+b$. Each permutation is equally likely. For each permutation in which red 1 precedes all the black balls there is another equally likely permutation, obtained by interchanging the red ball with the first of the black balls chosen; and there is an equally likely permutation in which it appears after two black balls, obtained by interchanging the red ball with the second of the black balls chosen; and so on. Formally, we are partitioning the whole sample space into equally likely events, each determined by a relative ordering of red 1 and all the black balls. There are $b+1$ such equally likely events, and their probabilities sum to one.

Now it is easy to calculate the expected value for red 1.

$$
\mathbb{E} T_{1}=0 \mathbb{P}\left\{T_{1}=0\right\}+1 \mathbb{P}\left\{T_{1}=1\right\}=1 /(b+1)
$$

The expected number of red balls removed before the first black ball is equal to $r /(b+1)$.

## Example 5.

Suppose two players, Alf (A for short) and Betamax (B for short), bet on the tosses of a fair coin: for a head, Alf pays Betamax one dollar; for a tail, Betamax pays Alf one dollar. They stop playing when one player runs out of money. If Alf starts with $\alpha$ dollar bills, and Betamax starts with $\beta$ dollars bills (both $\alpha$ and $\beta$ whole numbers), what is the probability that Alf ends up with all the money?

Write $X_{n}$ for the number of dollars held by A after $n$ tosses. (Of course, once the game ends the value of $X_{n}$ stays fixed from then on, at either $a+b$ or 0 , depending on whether A won or not.) It is a random variable taking values in the range $\{0,1,2, \ldots, a+b\}$. We start with $X_{0}=\alpha$. To solve the problem, calculate $\mathbb{E} X_{n}$, for very large $n$ in two ways, then equate the answers. We need to solve for the unknown $\theta=\mathbb{P}\{\mathrm{A}$ wins $\}$.

## First calculation.

Invoke rule (E4) with the sample space broken into three pieces,

$$
\begin{aligned}
& A_{n}=\{\mathrm{A} \text { wins at }, \text { or before, the } n \text {th toss }\}, \\
& B_{n}=\{\mathrm{B} \text { wins at, or before, the } n \text {th toss }\}, \\
& C_{n}=\{\text { game still going after the } n \text {th toss }\} .
\end{aligned}
$$

For very large $n$ the game is almost sure to be finished, with $\mathbb{P} A_{n} \approx \theta$, $\mathbb{P} B_{n} \approx 1-\theta$, and $\mathbb{P} C_{n} \approx 0$. Thus

$$
\begin{aligned}
\mathbb{E} X_{n} & =\mathbb{E}\left(X_{n} \mid A_{n}\right) \mathbb{P} A_{n}+\mathbb{E}\left(X_{n} \mid B_{n}\right) \mathbb{P} B_{n}+\mathbb{E}\left(X_{n} \mid C_{n}\right) \mathbb{P} C_{n} \\
& \approx((\alpha+\beta) \times \theta)+(0 \times(1-\theta))+((\text { something }) \times 0) .
\end{aligned}
$$

The error in the approximation goes to zero as $n$ goes to infinity.

## Second calculation.

Calculate conditionally on the value of $X_{n-1}$. That is, split the sample space into disjoint events $F_{k}=\left\{X_{n-1}=k\right\}$, for $k=0,1, \ldots, a+b$, then
work towards another appeal to rule (E4). For $k=0$ or $k=a+b$, the game will be over, and $X_{n}$ must take the same value as $X_{n-1}$. That is,

$$
\mathbb{E}\left(X_{n} \mid F_{0}\right)=0 \quad \text { and } \quad \mathbb{E}\left(X_{n} \mid F_{\alpha+\beta}\right)=\alpha+\beta
$$

For values of $k$ between the extremes, the game is still in progress. With the next toss, A's fortune will either increase by one dollar (with probability $1 / 2$ ) or decrease by one dollar (with probability $1 / 2$ ). That is, for $k=$ $1,2, \ldots, \alpha+\beta-1$,

$$
\mathbb{E}\left(X_{n} \mid F_{k}\right)=\frac{1}{2}(k+1)+\frac{1}{2}(k-1)=k .
$$

Now invoke (E4).

$$
E\left(X_{n}\right)=\left(0 \times \mathbb{P} F_{0}\right)+\left(1 \times \mathbb{P} F_{1}\right)+\cdots+(\alpha+\beta) \mathbb{P} F_{\alpha+\beta} .
$$

Compare with the direct application of (E5)' to the calculation of $E X_{n-1}$ :

$$
\begin{aligned}
\mathbb{E}\left(X_{n-1}\right)= & \left(0 \times \mathbb{P}\left\{X_{n-1}=0\right\}\right)+\left(1 \times \mathbb{P}\left\{X_{n-1}=1\right\}\right)+ \\
& \cdots+\left((\alpha+\beta) \times \mathbb{P}\left\{X_{n-1}=\alpha+\beta\right\}\right),
\end{aligned}
$$

which is just another way of writing the sum for $\mathbb{E} X_{n}$ derived above. Thus we have

$$
\mathbb{E} X_{n}=\mathbb{E} X_{n-1}
$$

The expected value doesn't change from one toss to the next.
Follow this fact back through all the previous tosses to get

$$
\mathbb{E} X_{n}=\mathbb{E} X_{n-1}=\mathbb{E} X_{n-2}=\cdots=\mathbb{E} X_{2}=\mathbb{E} X_{1}=\mathbb{E} X_{0}
$$

But $X_{0}$ is equal to $\alpha$, for certain, which forces $\mathbb{E} X_{0}=\alpha$.

## Putting the two answers together.

We have two results: $\mathbb{E} X_{n}=\alpha$, no matter how large $n$ is; and $\mathbb{E} X_{n}$ gets arbitrarily close to $\theta(\alpha+\beta)$ as $n$ gets larger. We must have $\alpha=\theta(\alpha+\beta)$. That is, Alf has probability $\alpha /(\alpha+\beta)$ of eventually winning all the money.

Danger: The next two Examples are harder. They can be skipped.

## Example 6.

Same problem as in Example $<5>$, except that the coin they toss has probability $p \neq 1 / 2$ of landing heads.

The cases $p=0$ and $p=1$ are trivial. So let us assume that $0<p<1$ (and $p \neq 1 / 2$ ). Essentially De Moivre's idea was that we could use almost the same method as in Example $<5>$ if we kept track of A's fortune on a geometrically expanding scaled. For some number $s$, to be specified soon, consider a new random variable $Z_{n}=s^{X_{n}}$

Once again write $\theta$ for $\mathbb{P}\{\mathrm{A}$ wins $\}$, and give the events $A_{n}, B_{n}$, and $C_{n}$ the same meaning as in Example $<5>$.

As in the first calculation for the other Example, we have

$$
\begin{aligned}
\mathbb{E} Z_{n} & =\mathbb{E}\left(s^{X_{n}} \mid A_{n}\right) \mathbb{P} A_{n}+\mathbb{E}\left(s^{X_{n}} \mid B_{n}\right) \mathbb{P} B_{n}+\mathbb{E}\left(s^{X_{n}} \mid C_{n}\right) \mathbb{P} C_{n} \\
& \approx\left(s^{\alpha+\beta} \times \theta\right)+\left(s^{0} \times(1-\theta)\right)+((\text { something }) \times 0)
\end{aligned}
$$

if $n$ is very large.
For the analog of the second calculation, in the cases where the game has ended by at or before the $(n-1)$ st toss we have

$$
\mathbb{E}\left(Z_{n} \mid X_{n-1}=0\right)=s^{0} \quad \text { and } \quad \mathbb{E}\left(Z_{n} \mid X_{n-1}=\alpha+\beta\right)=s^{\alpha+\beta}
$$

For $0<k<\alpha+\beta$, the result of the calculation is slightly different.

$$
\mathbb{E}\left(Z_{n} \mid X_{n-1}=k\right)=p s^{k+1}+(1-p) s^{k-1}=\left(p s+(1-p) s^{-1}\right) s^{k} .
$$

If we choose $s=(1-p) / p$, the factor $\left(p s+(1-p) s^{-1}\right)$ becomes 1 . Invoking rule E 4 we then get

$$
\begin{aligned}
\mathbb{E} Z_{n}= & \mathbb{E}\left(Z_{n} \mid X_{n-1}=0\right) \times \mathbb{P}\left(X_{n-1}=0\right)+\mathbb{E}\left(Z_{n} \mid X_{n-1}=1\right) \times \mathbb{P}\left(X_{n-1}=1\right) \\
& +\cdots+\mathbb{E}\left(Z_{n} \mid X_{n-1}=\alpha+\beta\right) \times \mathbb{P}\left(X_{n-1}=\alpha+\beta\right) \\
= & s^{0} \times \mathbb{P}\left(X_{n-1}=0\right)+s^{1} \times \mathbb{P}\left(X_{n-1}=1\right) \\
& +\cdots+s^{\alpha+\beta} \times \mathbb{P}\left(X_{n-1}=\alpha+\beta\right)
\end{aligned}
$$

Compare with the calculation of $\mathbb{E} Z_{n-1}$ via (E5).

$$
\begin{aligned}
\mathbb{E} Z_{n-1}= & \mathbb{E}\left(s^{X_{n-1}} \mid X_{n-1}=0\right) \times \mathbb{P}\left(X_{n-1}=0\right) \\
& +\mathbb{E}\left(s^{X_{n-1}} \mid X_{n-1}=1\right) \times \mathbb{P}\left(X_{n-1}=1\right) \\
& +\cdots+\mathbb{E}\left(s^{X_{n-1}} \mid X_{n-1}=\alpha+\beta\right) \times \mathbb{P}\left(X_{n-1}=\alpha+\beta\right) \\
= & s^{0} \times \mathbb{P}\left(X_{n-1}=0\right)+s^{1} \times \mathbb{P}\left(X_{n-1}=1\right)+\ldots \\
& +s^{\alpha+\beta} \times \mathbb{P}\left(X_{n-1}=\alpha+\beta\right)
\end{aligned}
$$

Once again we have a situation where $\mathbb{E} Z_{n}$ stays fixed at the initial value $\mathbb{E} Z_{0}=s^{\alpha}$, but, with very large $n$, it can be made arbitrarily close to $\theta s^{\alpha+\beta}+$ $(1-\theta) s^{0}$. Equating the two values, we deduce that

$$
\mathbb{P}\{\text { Alf wins }\}=\theta=\frac{1-s^{\alpha}}{1-s^{\alpha+\beta}} \quad \text { where } s=(1-p) / p
$$

What goes wrong with this calculation if $p=1 / 2$ ? As a check we could let $p$ tend to $1 / 2$, getting

$$
\begin{aligned}
\frac{1-s^{\alpha}}{1-s^{\alpha+\beta}} & =\frac{(1-s)\left(1+s+\cdots+s^{\alpha-1}\right)}{(1-s)\left(1+s+\cdots+s^{\alpha+\beta-1}\right)} \quad \text { for } s \neq 1 \\
& =\frac{1+s+\cdots+s^{\alpha-1}}{1+s+\cdots+s^{\alpha+\beta-1}} \\
& \rightarrow \frac{\alpha}{\alpha+\beta} \quad \text { as } s \rightarrow 1 .
\end{aligned}
$$

Comforted?

## Example 7.

My interest in the calculations in Example <4> was kindled by a problem that appeared in the August-September 1992 issue of the American

Mathematical Monthly. My solution to the problem - the one I first came up with by application of a straightforward conditioning argument-reduces the calculation to several applications of the result from the previous Example. The solution offered by two readers of the Monthly was slicker.

E 3429 [1991, 264]. Proposed by Donald E. Knuth and John McCarthy, Stanford University, Stanford, CA.

A certain pill bottle contains $m$ large pills and $n$ small pills initially, where each large pill is equivalent to two small ones. Each day the patient chooses a pill at random; if a small pill is selected, (s)he eats it; otherwise (s)he breaks the selected pill and eats one half, replacing the other half, which thenceforth is considered to be a small pill.
(a) What is the expected number of small pills remaining when the last large pill is selected?
(b) On which day can we expect the last large pill to be selected?

## Solution from AMM:.

Composite solution by Walter Stromquist, Daniel H. Wagner, Associates, Paoli, PA and Tim Hesterberg, Franklin $\mathcal{E}$ Marshall College, Lancaster, $P A$. The answers are (a) $n /(m+1)+\sum_{k=1}^{m}(1 / k)$, and (b) $2 m+n-(n /(m+$ 1)) $-\sum_{k=1}^{m}(1 / k)$. The answer to (a) assumes that the small pill created by breaking the last large pill is to be counted. A small pill present initially remains when the last large pill is selected if and only if it is chosen last from among the $m+1$ element set consisting of itself and the large pills - an event of probability $1 /(m+1)$. Thus the expected number of survivors from the original small pills is $n /(m+1)$. Similarly, when the $k$ th large pill is selected $(k=1,2, \ldots, m)$, the resulting small pill will outlast the remaining large pills with probability $1 /(m-k+1)$, so the expected number of created small pills remaining at the end is $\sum_{k=1}^{m}(1 / k)$. Hence the answer to (a) is as above. The bottle will last $2 m+n$ days, so the answer to (b) is just $2 m+n$ minus the answer to (a), as above.

I offer two alternative methods of solution for the problem. The first method uses a conditioning argument to set up a recurrence formula for the expected numbers of small pills remaining in the bottle after each return of half a big pill. The equations are easy to solve by repeated substitution. The second method uses indicator functions to spell out the HesterbergStromquist method in more detail. Apparently the slicker method was not as obvious to most readers of the Monthly (and me):
origins of the problem. Robert High saw a version of it in the MIT Technology Review of April, 1990. Helmut Prodinger reports that he proposed it in the Canary Islands in 1982. Daniel Moran attributes the problem to Charles MacCluer of Michigan State University, where it has been known for some time.
Solved by 38 readers (including those cited) and the proposer. One incorrect solution was received.

## Conditioning method..

Invent random variables to describe the depletion of the pills. Initially there are $L_{0}=n$ small pills in the bottle. Let $S_{1}$ small pills be consumed before the first large pill is broken. After the small half is returned to the bottle let there be $L_{1}$ small pills left. Then let $S_{2}$ small pills be consumed before the next big pill is split, leaving $L_{2}$ small pills in the bottle. And so on.

With this notation, part (a) is asking for $\mathbb{E} L_{m}$. Part (b) is asking for $2 m+n-\mathbb{E} L_{m}$ : If the last big pill is selected on day $X$ then it takes $X+L_{m}$ days to consume the $2 m+n$ small pill equivalents, so $\mathbb{E} X+\mathbb{E} L_{m}=2 m+n$.

The random variables are connected by the equation

$$
L_{i}=L_{i-1}-S_{i}+1
$$

the $-S_{i}$ representing the small pills consumed between the breaking of the $(i-1)$ st and $i$ th big pill, and the +1 representing the half of the big pill that is returned to the bottle. Taking expectations we get

$$
\mathbb{E} L_{i}=\mathbb{E} L_{i-1}-\mathbb{E} S_{i}+1
$$

The result from Example $<4>$ will let us calculate $\mathbb{E} S_{i}$ in terms of $\mathbb{E} L_{i-1}$, thereby producing the recurrence formula for $\mathbb{E} L_{i}$.

Condition on the pill history up to the $(i-1)$ st breaking of big pill (and the return of the unconsumed half to the bottle). At that point there are $L_{i-1}$ small pills and $m-(i-1)$ big pills in the bottle. The mechanism controlling $S_{i}$ is just like the urn problem of Example $<4>$, with

$$
\begin{aligned}
r & =L_{i-1} \text { red balls }(=\text { small pills }) \\
b & =m-(i-1) \text { black balls }(=\mathrm{big} \text { pills })
\end{aligned}
$$

From that Example,

$$
\mathbb{E}\left\{S_{i} \mid \text { history to }(i-1) \text { st breaking of a big pill }\right\}=L_{i-1} 1+m-(i-1) .
$$

To calculate $\mathbb{E} S_{i}$ we would need to average out using weights equal to the probability of each particular history:

$$
\mathbb{E} S_{i}=\frac{1}{1+m-(i-1)} \sum_{\text {histories }} \mathbb{P}\{\text { history }\}\left(\text { value of } L_{i-1}\right. \text { for that history). }
$$

The sum on the right-hand side is exactly the sum we would get if we calculated $\mathbb{E} L_{i-1}$ using rule $\mathbb{E} 4$, partitioning the sample space according to possible histories up to the $(i-1)$ st breaking of a big pill. Thus

$$
\mathbb{E} S_{i}=\frac{1}{2+m-i} \mathbb{E} L_{i-1} .
$$

Now we can eliminate $\mathbb{E} S_{i}$ from equality $\langle 8\rangle$ to get the recurrence formula for the $\mathbb{E} L_{i}$ values:

$$
\mathbb{E} L_{i}=\left(1-\frac{1}{2+m-i}\right) \mathbb{E} L_{i-1}+1
$$

If we define $\theta_{i}=\mathbb{E} L_{i} /(1+m-i)$ the equation becomes

$$
\theta_{i}=\theta_{i-1}+\frac{1}{1+m-i} \quad \text { for } i=1,2, \ldots, m
$$

with initial condition $\theta_{0}=\mathbb{E} L_{0} /(1+m)=n /(1+m)$. Repeated substitution gives

$$
\begin{aligned}
& \theta_{1}=\theta_{0}+\frac{1}{m} \\
& \theta_{2}=\theta_{1}+\frac{1}{m-1}=\theta_{0}+\frac{1}{m}+\frac{1}{m-1} \\
& \theta_{3}=\theta_{2}+\frac{1}{m-2}=\theta_{0}+\frac{1}{m}+\frac{1}{m-1}+\frac{1}{m-2} \\
& \vdots \\
& \theta_{m}=\cdots=\theta_{0}+\frac{1}{m}+\frac{1}{m-1}+\cdots+\frac{1}{2}+\frac{1}{1} .
\end{aligned}
$$

That is, the expected number of small pills left after the last big pill is broken equals

$$
\begin{aligned}
\mathbb{E} L_{m} & =(1+m-m) \theta_{m} \\
& =\frac{n}{1+m}+1+\frac{1}{2}+\cdots+\frac{1}{m} .
\end{aligned}
$$

## Rewrite of the Stromquist-Hesterberg solution..

Think in terms of half pills, some originally part of big pills. Number the original half pills $1, \ldots, n$. Define

$$
H_{i}= \begin{cases}+1 & \text { if original half pill } i \text { survives beyond last big pill } \\ 0 & \text { otherwise. }\end{cases}
$$

Number the big pills $1, \ldots, m$. Use the same numbers to refer to the half pills that are created when a big pill is broken. Define

$$
B_{j}= \begin{cases}+1 & \text { if created half pill } j \text { survives beyond last big pill } \\ 0 & \text { otherwise. }\end{cases}
$$

The number of small pills surviving beyond the last big pill equals

$$
H_{1}+\cdots+H_{n}+B_{1}+\cdots+B_{m} .
$$

By symmetry, each $H_{i}$ has the same expected value, as does each $B_{j}$. The expected value asked for by part (a) equals

$$
n \mathbb{E} H_{1}+m \mathbb{E} B_{1}=n \mathbb{P}\left\{H_{1}=1\right\}+m \mathbb{P}\left\{B_{1}=1\right\}
$$

For the calculation of $\mathbb{P}\left\{H_{1}=+1\right\}$ we can ignore all except the relative ordering of the $m$ big pills and the half pill described by $H_{1}$. By symmetry, the half pill has probability $1 /(m+1)$ of appearing in each of the $m+1$ possible positions in the relative ordering. In particular,

$$
\mathbb{P}\left\{H_{1}=+1\right\}=\frac{1}{m+1} .
$$

For the created half pills the argument is slightly more complicated. If we are given that big pill number 1 the kth amongst the big pills to be broken, the created half then has to survive beyond the remaining $m-k$ big pills. Arguing again by symmetry amongst the $(m-k+1)$ orderings we get

$$
\mathbb{P}\left\{B_{1}=+1 \mid \text { big number } 1 \text { chosen as kth big }\right\}=\frac{1}{m-k+1} .
$$

Also by symmetry,

$$
\mathbb{P}\{\text { big } 1 \text { chosen as kth big }\}=\frac{1}{m} .
$$

Average out using the conditioning rule E4 to deduce

$$
\mathbb{P}\left\{B_{1}=+1\right\}=\frac{1}{m} \sum_{k=1}^{m} \frac{1}{m-k+1} .
$$

Notice that the summands run through the values $1 / 1$ to $1 / m$ in reversed order.

When the values for $\mathbb{P}\left\{H_{1}=+1\right\}$ and $\mathbb{P}\left\{B_{1}=+1\right\}$ are substituted into $\langle 9\rangle$, the asserted answer to part (a) results.

## Appendix: The fair price interpretation of expectations.

Consider a situation - a bet if you will-where you stand to receive an uncertain return $X$. You could think of $X$ as a random variable, a real-valued function on a sample space $S$. For the moment forget about any probabilities on the sample space $S$. Suppose you consider $p(X)$ the fair price to pay in order to receive $X$. What properties must $p(\cdot)$ have?

Your net return will be the random quantity $X-p(X)$, which you should consider to be a fair return. Unless you start worrying about the utility of money you should find the following properties reasonable.
(i) fair + fair $=$ fair. That is, if you consider $p(X)$ fair for $X$ and $p(Y)$ fair for $Y$ then you should be prepared to make both bets, paying $p(X)+p(Y)$ to receive $X+Y$.
(ii) constant $\times$ fair $=$ fair. That is, you shouldn't object if I suggest you pay $2 p(X)$ to receive $2 X$ (actually, that particular example is a special case of (i)) or $3.76 p(X)$ to receive $3.76 X$, or $-p(X)$ to receive $-X$. The last example corresponds to willingness to take either side of a fair bet. In general, to receive $c X$ you should pay $c p(X)$, for constant $c$.
(iii) There is no fair bet whose return $X-p(X)$ is always $\geq 0$ (except for the trivial situation where $X-p(X)$ is certain to be zero).

If you were to declare a bet with return $X-p(X) \geq 0$ under all circumstances to be fair, I would be delighted to offer you the opportunity to receive the "fair" return $-C(X-p(X))$, for an arbitrarily large positive constant $C$. I couldn't lose.

Fact 1: Properties (i), (ii), and (iii) imply that $p(\alpha X+\beta Y)=\alpha p(X)+$ $\beta p(Y)$ for all random variables $X$ and $Y$, and all constants $\alpha$ and $\beta$.

Consider the combined effect of the following fair bets:
you pay me $\alpha p(X)$ to receive $\alpha X$
you pay me $\beta p(Y)$ to receive $\beta Y$
I pay you $p(\alpha X+\beta Y)$ to receive $(\alpha X+\beta Y)$.

Your net return is a constant,

$$
c=p(\alpha X+\beta Y)-\alpha p(X)-\beta p(Y)
$$

If $c>0$ you violate (iii); if $c<0$ take the other side of the bet to violate (iii). The asserted equality follows.

Fact 2: Properties (i), (ii), and (iii) imply that $p(Y) \leq p(X)$ if the random variable $Y$ is always $\leq$ the random variable $X$.

If you claim that $p(X)<p(Y)$ then I would be happy for you to accept the bet that delivers

$$
(Y-p(Y))-(X-p(X))=-(X-Y)-(p(Y)-p(X)),
$$

which is always $<0$.
The two Facts are analogous to rules E1 and E3 for expectations. You should be able to deduce the analog of E2 from (iii).

As a special case, consider the bet that returns 1 if an event $F$ occurs, and 0 otherwise. If you identify the event $F$ with the random variable taking the value 1 on $F$ and 0 on $F^{c}$ (that is, the indicator of the event $F$ ), then it follows directly from Fact 1 that $p(\cdot)$ is additive: $p\left(F_{1} \cup F_{2}\right)=p\left(F_{1}\right)+p\left(F_{2}\right)$ for disjoint events $F_{1}$ and $F_{2}$, an analog of rule P 4 for probabilities.

## Contingent bets.

Things become much more interesting if you are prepared to make a bet to receive an amount $X$, but only when some event $F$ occurs. That is, the bet is made contingent on the occurrence of $F$. Typically, knowledge of the occurrence of $F$ should change the fair price, which we could denote by $p(X \mid F)$. Let me write $Z$ for the indicator function of the event $F$, that is,

$$
Z= \begin{cases}1 & \text { if event } F \text { occurs } \\ 0 & \text { otherwise }\end{cases}
$$

Then the net return from the contingent bet is $(X-p(X \mid F)) Z$. The indicator function $Z$ ensures that money changes hands only when $F$ occurs.

By combining various bets and contingent bets, we can deduce that an analog of rule E4 for expectations: if $S$ is partitioned into disjoint events $F_{1}, \ldots, F_{k}$, then

$$
p(X)=\sum_{i=1}^{k} p\left(F_{i}\right) p\left(X \mid F_{i}\right) .
$$

Make the following bets. Write $c_{i}$ for $p\left(X \mid F_{i}\right)$.
(a) For each $i$, pay $c_{i} p\left(F_{i}\right)$ in order to receive $c_{i}$ if $F_{i}$ occurs. ritem[(b)] Pay $-p(X)$ in order to receive $-X$.
(c) For each $i$, make a bet contingent on $F_{i}$ : pay $c_{i}$ (if $F_{i}$ occurs) to receive $X$.

If event $F_{k}$ occurs, your net profit will be

$$
-\sum_{i} c_{i} p\left(F_{i}\right)+c_{k}+p(X)-X-c_{k}+X=p(X)-\sum_{i} c_{i} p\left(F_{i}\right)
$$

which does not depend on $k$. Your profit is always the same constant value. If the constant were nonzero, requirement (iii) for fair bets would be violated.

If you rewrite $p(X)$ as the expected value $\mathbb{E} X$, and $p(F)$ as $\mathbb{P} F$ for an event $F$, and $\mathbb{E}(X \mid F)$ for $p(X \mid F)$, you will see that the properties of fair prices are completely analogous to the rules for probabilities and expectations. Some authors take the bold step of interpreting probability theory as a calculus of fair prices. The interpretation has the virtue that it makes sense in some situations where there is no reasonable way to imagine an unlimited sequence of repetions from which to calculate a long-run frequency or average.

See de Finetti (1974) for a detailed discussion of expectations as fair prices.

## Chapter 3

## Things binomial

The standard coin-tossing mechanism drives much of classical probability. It generates several standard distributions, the most important of them being the Binomial. The name comes from the binomial coefficient, $\binom{n}{k}$, which is defined as the number of subsets of size $k$ for a set of size $n$. (Read the symbol as " $n$ choose $k$ ".) By convention, $\binom{n}{0}=1$.

There is a quick probabilistic way to determine $\binom{n}{k}$, for integers $1 \leq k \leq$ $n$. Suppose $k$ balls are sampled at random, without replacement, from an urn containing $k$ red balls and $n-k$ black balls. Each of the $\binom{n}{k}$ different subsets of size $k$ has probability $1 /\binom{n}{k}$ of being selected. In particular, there is probabilty $1 /\binom{n}{k}$ that the sample consists of the red balls. We can also calculate this probability using a conditioning argument. Given that the first $i$ balls are red, the probability that the $(i+1)$ st is red is $(k-i) /(n-i)$. Thus

$$
\frac{k}{n} \cdot \frac{k-1}{n-1} \cdot \frac{k-2}{n-2} \cdots \frac{1}{n-k+1}
$$

Equating the two values for $\mathbb{P}$ \{sample consists of all red balls $\}$, we get

$$
\binom{n}{k}=\frac{n(n-1) \ldots(n-k+1)}{k!}=\frac{n!}{k!(n-k)!}
$$

The formula also holds for $k=0$ if we interpret 0 ! as 1 .
Remark. The symbol $\binom{n}{k}$ is called a binomial coefficient because of its connection with the binomial expansion: $(a+b)^{n}=\sum_{k=0}^{n}\binom{n}{k} a^{k} b^{n-k}$. The expansion can be generalized to fractional and negative powers by means of Taylor's theorem. For general real $\alpha$ define

$$
\binom{\alpha}{0}=1 \quad \text { and } \quad\binom{\alpha}{k}=\frac{\alpha(\alpha-1)(\alpha-2) \ldots(\alpha-k+1)}{k!} \quad \text { for } k=1,2, \ldots
$$

Then

$$
(1+x)^{\alpha}=\sum_{k=0}^{\infty}\binom{\alpha}{k} x^{k} \quad \text { at least for }|x|<1
$$

Definition. (Binomial distribution) A random variable is said to have a $\operatorname{Bin}(n, p)$ distribution, for a parameter $p$ in the range $0 \leq p \leq 1$, if can take values $0,1, \ldots, n-1, n$ with probabilities

$$
\mathbb{P}\{X=k\}=\binom{n}{k} p^{k}(1-p)^{n-k} \quad \text { for } k=0,1, \ldots, n
$$

Compare with the binomial expansion,

$$
1=(p+q)^{n}=\sum_{k=0}^{n}\binom{n}{k} p^{k} q^{n-k} \quad \text { where } q=1-p
$$

$<1>\quad$ Example. For n independent tosses of a coin that lands heads with probability $p$, show that the total number of heads has a $\operatorname{Bin}(n, p)$ distribution, with expected value $n p$.

The Binomial distribution arises in any situation where one is interested in the number of successes in a fixed number of independent trials (or experiments), each of which can result in either success or failure.
$<2>\quad$ Example. An unwary visitor to the Big City is standing at the corner of 1st Street and 1st Avenue. He wishes to reach the railroad station, which actually occupies the block on 6th Street from 3rd to 4th Avenue. (The Street numbers increase as one moves north; the Avenue numbers increase as one moves east.) He is unaware that he is certain to be mugged as soon as he steps onto 6th Street or 6th Avenue.

Being unsure of the exact location of the railroad station, the visitor lets himself be guided by the tosses of a fair coin: at each intersection he goes east, with probability $1 / 2$, or north, with probability $1 / 2$. What is the probability that he is mugged outside the railroad station?

The following problem is an example of Bayesian inference, based on the probabilistic result known as Bayes's rule. You need not memorize the rule, because it is just an application of the conditioning method you already know.
$<3>$
Example. Suppose a multiple-choice exam consists of a string of unrelated questions, each having three possible answers. Suppose there are two types of candidate who will take the exam: guessers, who make a blind stab on each question, and skilled candidates, who can always eliminate one obviously false alternative, but who then choose at random between the two remaining alternatives. Suppose $70 \%$ of the candidates who take the exam are skilled and the other $30 \%$ are guessers. A particular candidate has gotten 4 of the first 6 question correct. What is the probability that he will also get the 7th question correct?

As a method of solving statistical problems, Bayesian inference is advocated devoutly by some Statisticians, and derided by others. There is no disagreement regarding the validity of Bayes's rule; it is the assignment of prior probabilities - such as the $\mathbb{P} S$ and $\mathbb{P} G$ of the previous Example-that is controversial in a general setting.

The Bayesian message comes through more strongly in the next Example.
$<4>\quad$ Example. Suppose we have three coins, which land heads with probabilities $p_{1}, p_{2}$, and $p_{3}$. Choose a coin according to the prior distribution $\theta_{i}=\mathbb{P}\{$ choose coin $i\}$, for $i=1,2,3$, then toss that coin $n$ times. Find the posterior probabilities $\mathbb{P}\{$ chose coin $i \mid k$ heads with $n$ tosses $\}$, for $k=0,1, \ldots, n$.

To retain a neutral statistical position, I should also give an example of a different approach to statistical inference. The example just happens to involve the Binomial distribution again.
$<5>$ Example. Members of the large governing body of a small country are given special banking privileges. Unfortunately, some members appear to be abusing the privilege by writing bad checks. The royal treasurer declares the abuse to be a minor aberration, restricted to fewer than $5 \%$ of the members. An investigative reporter manages to expose the bank records of 20 members, showing that 4 of them have been guilty. How credible is the treasurer's assertion?

We will meet the Binomial again.

## Example 1.

For $n$ independent tosses of a coin that lands heads with probability $p$, show that the total number of heads has a $\operatorname{Bin}(n, p)$ distribution, with expected value $n p$.

Clearly $X$ can take only values $0,1,2, \ldots, n$. For a fixed a $k$ in this range, break the event $\{X=k\}$ into disjoint pieces like
$F_{1}=\{$ first k gives heads, next $\mathrm{n}-\mathrm{k}$ give tails $\}$
$F_{2}=\{$ first (k-1) give heads, then tail, then head, then n- k-1 tails $\}$
:

Here $i$ runs from 1 to $\binom{n}{k}$, because each $F_{i}$ corresponds to a different choice of the $k$ positions for the heads to occur. (The indexing on the $F_{i}$ is most uninformative; it gives no indication of the corresponding pattern of heads and tails. Maybe you can think of something better.) Write $H_{j}$ for $\{j$ jth toss is a head\}. Then

$$
\begin{aligned}
\mathbb{P} F_{1} & =\mathbb{P}\left(H_{1} H_{2} \ldots H_{k} H_{k+1}^{c} \ldots H_{n}^{c}\right) \\
& =\left(\mathbb{P} H_{1}\right)\left(\mathbb{P} H_{2}\right) \ldots\left(\mathbb{P} H_{n}^{c}\right) \quad \text { by independence } \\
& =p^{k}(1-p)^{n-k} .
\end{aligned}
$$

A similar calculation gives $\mathbb{P} F_{i}=p^{k}(1-p)^{n-k}$ for every other $i$; all that changes is the order in which the $p$ and $(1-p)$ factors appear. Thus

$$
\mathbb{P}\{X=k\}=\binom{n}{k} p^{k}(1-p)^{n-k} \quad \text { for } k=0,1, \ldots, n,
$$

which is the asserted Binomial distribution.
It is possible to calculate $\mathbb{E} X$ by the summation formula

$$
\begin{aligned}
\mathbb{E} X & =\sum_{k=0}^{n} \mathbb{E}(X \mid X=k) \mathbb{P}\{X=k\} \\
& =\sum_{k=0}^{n} k\binom{n}{k} p^{k}(1-p)^{n-k} \\
& =\sum_{k=1}^{n} \frac{n(n-1)!}{(k-1)!(n-k)!} p^{k}(1-p)^{n-k} \\
& =n p \sum_{k-1=0}^{n-1}\binom{n-1}{k-1} p^{k-1}(1-p)^{(n-1)-(k-1)} \\
& =n p \quad \text { cf. binomial expansion of }(p+(1-p))^{n-1} .
\end{aligned}
$$

The manipulations of the sums was only slightly tedious, but why endure even a little tedium when the method of indicators is so much simpler? Define

$$
X_{i}= \begin{cases}1 & \text { if ith toss is head } \\ 0 & \text { if ith toss is tail. }\end{cases}
$$

Then $X=X_{1}+\ldots X_{n}$, which gives $\mathbb{E} X=\mathbb{E} X_{1}+\ldots \mathbb{E} X_{n}=n \mathbb{E} X_{1}$. Calculate.

$$
\mathbb{E} X_{1}=0 \mathbb{P}\left\{X_{1}=0\right\}+1 \mathbb{P}\left\{X_{1}=1\right\}=p .
$$

Thus $\mathbb{E} X=n p$.
Remark. The calculation made no use of the independence. If each $X_{i}$ has marginal distribution $\operatorname{Bin}(1, p)$, that is, if

$$
\mathbb{P}\left\{X_{i}=1\right\}=p=1-\mathbb{P}\left\{X_{i}=0\right\} \quad \text { for each } i,
$$

then $\mathbb{E}\left(X_{1}+\ldots X_{n}\right)=n p$, regardless of possible dependence between the tosses. The expectation of a sum is the sum of the expectations, no matter how dependent the summands might be.

## Example 2.

6

An unwary visitor to the Big City is standing at the corner of 1st Street and 1st Avenue. He wishes to reach the railroad station, which actually occupies the block on 6th Street from 3rd to 4th Avenue. (The Street numbers increase as one moves north; the Avenue numbers increase as one moves east.) He is unaware that he is certain to be mugged as soon as he steps onto 6th Street or 6th Avenue.

Being unsure of the exact location of the railroad station, the visitor lets himself be guided by the tosses of a fair coin: at each intersection he goes east, with probability $1 / 2$, or north, with probability $1 / 2$. What is the probability that he is mugged outside the railroad station?

To get mugged at $(3,6)$ or $(4,6)$ the visitor must proceed north from either the intersection $(3,5)$ or the intersection $(4,5)$-we may assume that if he gets mugged at $(2,6)$ and then moves east, he won't get mugged again at $(3,6)$, which would be an obvious waste of valuable mugging time for no return. The two possibilities correspond to disjoint events.

$$
\begin{aligned}
& \mathbb{P}\{\text { mugged at railroad }\} \\
& =\mathbb{P}\{\text { reach }(3,5), \text { move north }\}+\mathbb{P}\{\text { reach }(4,5), \text { move north }\} \\
& =\frac{1}{2} \mathbb{P}\{\text { reach }(3,5)\}+\frac{1}{2} \mathbb{P}\{\text { reach }(4,5)\} \\
& =\frac{1}{2} \mathbb{P}\{\text { move east twice during first } 6 \text { blocks }\} \\
& \quad+\frac{1}{2} \mathbb{P}\{\text { move east } 3 \text { times during first } 7 \text { blocks }\} .
\end{aligned}
$$

A better way to describe the last event might be "move east 3 times and north 4 times, in some order, during the choices governed by the first 7 tosses of the coin." The $\operatorname{Bin}(7,1 / 2)$ lurks behind the calculation. The other calculation involves the $\operatorname{Bin}(6,1 / 2)$.
$\mathbb{P}\{$ mugged at railroad $\}=\frac{1}{2}\binom{6}{2}\left(\frac{1}{2}\right)^{2}\left(\frac{1}{2}\right)^{4}+\frac{1}{2}\binom{7}{3}\left(\frac{1}{2}\right)^{3}\left(\frac{1}{2}\right)^{4}=\frac{65}{256}$.

Remark. Notice that the events $\{$ reach $(3,5)\}$ and $\{$ reach $(4,5)\}$ are not disjoint. We need to include the part about moving north to get a clean break.

## Example 3.

Suppose a multiple-choice exam consists of a string of unrelated questions, each having three possible answers. Suppose there are two types of candidate who will take the exam: guessers, who make a blind stab on each question, and skilled candidates, who can always eliminate one obviously false alternative, but who then choose at random between the two remaining alternatives. Suppose $70 \%$ of the candidates who take the exam are skilled and the other $30 \%$ are guessers. A particular candidate has gotten 4 of the first 6 question correct. What is the probability that he will also get the 7th question correct?

Interpret the assumptions to mean that a guesser answers questions independently, with probability $1 / 3$ of being correct, and that a skilled candidate also answers independently, but with probability $1 / 2$ of being correct. Let $X$ denote the number of questions answered correctly from the first six. Let $C$ denote the event \{question 7 answered correctly\}, $G$ denote the event $\{$ the candidate is a guesser\}, and $S$ denote the event \{the candidate is skilled\}. Then
(i) for a guesser, X has (conditional) distribution $\operatorname{Bin}(6,1 / 3)$
(ii) for a skilled candidate, X has (conditional) distribution $\operatorname{Bin}(6,1 / 2)$.
(iii) $\mathbb{P} G=0.3$ and $\mathbb{P} S=0.7$.

The question asks for $\mathbb{P}(C \mid X=4)$.
Split according to the type of candidate, then condition.

$$
\begin{aligned}
\mathbb{P}(C \mid X=4)= & \mathbb{P}\{C S \mid X=4\}+\mathbb{P}\{C G \mid X=4\} \\
= & \mathbb{P}(S \mid X=4) \mathbb{P}(C \mid X=4, S) \\
& +\mathbb{P}(G \mid X=4) \mathbb{P}(C \mid X=4, G)
\end{aligned}
$$

If we know the type of candidate, the $\{X=4\}$ information becomes irrelevant. The last expression simplifies to

$$
\frac{1}{2} \mathbb{P}(S \mid X=4)+1 / 3 \mathbb{P}(G \mid X=4)
$$

Notice how the success probabilities are weighted by probabilities that summarize our current knowledge about whether the candidate is skilled or guessing. If the roles of $\{X=4\}$ and type of candidate were reversed we could use the conditional distributions for $X$ to calculate conditional probabilities:

$$
\begin{aligned}
& \mathbb{P}(X=4 \mid S)=\binom{6}{4}\left(\frac{1}{2}\right)^{4}\left(\frac{1}{2}\right)^{2}=\binom{6}{4} 1 / 64 \\
& \mathbb{P}(X=4 \mid G)=\binom{6}{4}(1 / 3)^{4}(2 / 3)^{2}=\binom{6}{4}^{4 / 729 .}
\end{aligned}
$$

I have been lazy with the binomial coefficients because they will later cancel out.

Apply the usual splitting/conditioning argument.

$$
\begin{aligned}
\mathbb{P}(S \mid X=4) & =\frac{\mathbb{P} S\{X=4\}}{\mathbb{P}\{X=4\}} \\
& =\frac{\mathbb{P}(X=4 \mid S) \mathbb{P} S}{\mathbb{P}(X=4 \mid S) \mathbb{P} S+\mathbb{P}(X=4 \mid G) \mathbb{P} G} \\
& =\frac{\binom{6}{4} 1 / 64(.7)}{\binom{6}{4} 1 / 64(.7)+\binom{6}{4}^{4 / 729}(.3)} \\
& \approx .869 .
\end{aligned}
$$

There is no need to repeat the calculation for the other conditional probability, because

$$
\mathbb{P}(G \mid X=4)=1-\mathbb{P}(S \mid X=4) \approx .131
$$

Thus, given the 4 out of 6 correct answers, the candidate has conditional probability of approximately

$$
\frac{1}{2}(.869)+1 / 3(.131) \approx .478
$$

of answering the next question correctly.
Remark. Some authors prefer to summarize the calculations by means of the odds ratios:

$$
\frac{\mathbb{P}(S \mid X=4)}{\mathbb{P}(G \mid X=4)}=\frac{\mathbb{P} S}{\mathbb{P} G} \cdot \frac{\mathbb{P}(X=4 \mid S)}{\mathbb{P}(X=4 \mid G)}
$$

The initial odds ratio, $\mathbb{P} S / \mathbb{P} G$, is multiplied by a factor that reflects the relative support of the data for the two competing explanations "skilled" and "guessing".

## Example 4.

Suppose we have three coins, which land heads with probabilities $p_{1}, p_{2}$, and $p_{3}$. Choose a coin according to the prior distribution $\theta_{i}=\mathbb{P}\{$ chose coin $i\}$, for $i=1,2,3$, then toss that coin $n$ times. Find the posterior probabilities
$\mathbb{P}\{$ chose coin $i \mid k$ heads with $n$ tosses $\} \quad$ for $k=0,1, \ldots, n$.
Let $C_{i}$ denote the event $\{$ choose coin $i\}$ and $D_{k}$ denote the event that we get $k$ heads from the $n$ tosses. Then $\mathbb{P} C_{i}=\theta_{i}$ and

$$
\mathbb{P}\left(D_{k} \mid C_{i}\right)=\binom{n}{k} p_{i}^{k}\left(1-p_{i}\right)^{n-k} \quad \text { for } k=0,1, \ldots, n .
$$

Condition.

$$
\begin{aligned}
\mathbb{P}\left(C_{i} \mid D_{k}\right) & =\frac{\mathbb{P}\left(C_{i} D_{k}\right)}{\mathbb{P} D_{k}} \\
& =\frac{\mathbb{P}\left(D_{k} \mid C_{i}\right) \mathbb{P}\left(C_{i}\right)}{\sum_{j=1}^{3} \mathbb{P}\left(D_{k} \mid C_{j}\right) \mathbb{P}\left(C_{j}\right)} \\
& =\frac{p_{i}^{k}\left(1-p_{i}\right)^{n-k} \theta_{i}}{\sum_{j=1}^{3} p_{j}^{k}\left(1-p_{j}\right)^{n-k} \theta_{j}}
\end{aligned}
$$

Notice that the $\binom{n}{k}$ factors have cancelled. In fact, we would get the same posterior probabilities if we conditioned on any particular pattern of $k$ heads and $n-k$ tails.

The R-script Bayes.R defines functions to plot the posterior probabilities as a function of $k / n$, for various choices of the $p_{i}$ 's and the $\theta_{i}$ 's and $n$. The small circles in the plots correspond to the values $\mathbb{P}\left(C_{1} \mid D_{k}\right)$, the small triangles to $\mathbb{P}\left(C_{2} \mid D_{k}\right)$, and the small + signs to $\mathbb{P}\left(C_{3} \mid D_{k}\right)$. For the pictures I chose $p_{1}=0.45, p_{2}=0.5$ and $p_{3}=0.55$ with prior probabilities $\theta_{1}=0.5, \theta_{2}=0.3$, and $\theta_{3}=0.2$.
draw. posterior ( $\mathrm{p}=\mathrm{c}(0.45,0.5,0.55$ ), prior=c $(0.5,0.3,0.2)$, tosses=c $(10,50)$ )

draw. posterior $(\mathrm{p}=\mathrm{c}(0.45,0.5,0.55)$, $\operatorname{prior}=c(0.5,0.3,0.2)$, tosses=c $(100,500)$ )

When $n$ gets large, the posterior probability $\mathbb{P}\left(C_{i} \mid D_{k}\right)$ gets closer to 1 for values of $k / n$ close to $p_{i}$. Is that a comforting fact?

## Example 5.

Members of the large governing body of a small country are given special banking privileges. Unfortunately, some members appear to be abusing the privilege by writing bad checks. The royal treasurer declares the abuse to be a minor aberration, restricted to fewer than $5 \%$ of the members. An investigative reporter manages to expose the bank records of 20 members, showing that 4 of them have been guilty. How credible is the treasurer's assertion?

Suppose a fraction $p$ of the members are guilty. If the sample size 20 is small relative to the size of the legislature, and if the reporter samples at random from its members, the number of guilty in the sample should be distributed $\operatorname{Bin}(20, p)$. You should be able to think of many ways in
which these assumptions could be violated, but I'll calculate as if the simple Binomial model were correct.

Write $X$ for the number of guilty in the sample, and add a subscript $p$ to the probabilities to show that they refer to the $\operatorname{Bin}(20, p)$ distribution. Also write $q$ for $1-p$. Before the sample is taken we could assert

$$
\begin{aligned}
& \mathbb{P}_{p}\{X \geq 4\} \\
& \quad=\binom{20}{4} p^{4} q^{16}+\binom{20}{5} p^{5} q^{14}+\cdots+\binom{20}{4} p^{20} q^{0} \\
& \quad=1-\left[\binom{20}{0} p^{0} q^{20}+\binom{20}{1} p^{1} q^{19}+\binom{20}{2} p^{2} q^{18}+\binom{20}{3} p^{3} q^{17}\right] .
\end{aligned}
$$

The second form makes it easier to calculate by hand when $p=.05$ :

$$
\mathbb{P}_{.05}\{X \geq 4\} \approx .02
$$

For values of $p$ less than 0.05 the probability is even smaller.
After the sample is taken we are faced with a choice: either the treasurer is right, and we have just witnessed something very unusual; or maybe we should disbelieve the $5 \%$ upper bound. This dichotomy illustrates the statistical procedure called hypothesis testing. One chooses an event that should be rare under one model (the so-called null hypothesis), but more likely under an alternative model. If the event occurs, it casts doubt on the validity of the null hypothesis. For the present example the event $\{X \geq 4\}$ would have been much more likely under alternative explanations involving larger proportions of bad-check writers amongst the members of the legislature.

## Chapter 4

## Variances and covariances

The expected value of a random variable gives a crude measure for the "center of location" of the distribution of that random variable. For instance, if the distribution is symmetric about a value $\mu$ then the expected value equals $\mu$. To refine the picture of a distribution distributed about its "center of location" we need some measure of spread (or concentration) around that value. The simplest measure to calculate for many distributions is the variance (or, more precisely, the square root of the variance).

Definition. The variance of a random variable X with expected value $\mathbb{E} X=\mu$ is defined as $\operatorname{var}(X)=\mathbb{E}\left((X-\mu)^{2}\right)$. The square root of the variance of a random variable is called its standard deviation, sometimes denoted by $\operatorname{sd}(X)$.

The variance of a random variable $X$ is unchanged by an added constant: $\operatorname{var}(X+C)=\operatorname{var}(X)$ for every constant $C$, because $(X+C)-\mathbb{E}(X+C)=$ $X-\mathbb{E} X$, the $C$ 's cancelling. It is a desirable property that the spread should not be affected by a change in location. However, it is also desirable that multiplication by a constant should change the spread: $\operatorname{var}(C X)=$ $C^{2} \operatorname{var}(X)$ and $\operatorname{sd}(C X)=|C| \operatorname{sd}(X)$, because $(C X-\mathbb{E}(C X))^{2}=C^{2}(X-$ $\mathbb{E} X)^{2}$. In summary: for constants $a$ and $b$,

$$
\operatorname{var}(a+b X)=b^{2} \operatorname{var}(X) \quad \text { and } \quad \operatorname{sd}(a+b X)=|b| \operatorname{sd}(X) .
$$

Remark. Try not to confuse properties of expected values with properties of variances: for constants $a$ and $b$ we have $\operatorname{var}(a+b X)=$ $b^{2} \operatorname{var}(X)$ but $\mathbb{E}(a+b X)=a+b \mathbb{E} X$. Measures of location (expected value) and spread (standard deviation) should react differently to linear transformations of the variable. As another example: if a given piece of "information" implies that a random variable $X$ must take the constant value $C$ then $\mathbb{E}(X \mid$ information $)=C$, but $\operatorname{var}(X \mid$ information $)=0$.

It is a common blunder to confuse the formula for the variance of a difference with the formula $\mathbb{E}(Y-Z)=\mathbb{E} Y-\mathbb{E} Z$. If you ever find yourself wanting to assert that $\operatorname{var}(Y-Z)$ is equal to $\operatorname{var}(Y)-\operatorname{var}(Z)$, think again. What would happen if $\operatorname{var}(Z)$ were larger than $\operatorname{var}(Y)$ ? Variances can't be negative.

There is an enormous body of probability literature that deals with approximations to distributions, and bounds for probabilities, expressible in terms of expected values and variances. One of the oldest and simplest examples, the Tchebychev inequality, is still useful, even though it is rather crude by modern standards.
$<1>\quad$ Example. The Tchebychev inequality: $\mathbb{P}\{|X-\mu| \geq \epsilon\} \leq \operatorname{var}(X) / \epsilon^{2}$, where $\mu=\mathbb{E} X$ and $\epsilon>0$.

Remark. In the Chapter on the normal distribution you will find more refined probability approximations involving the variance.

The Tchebychev inequality gives the right insight when dealing with sums of random variables, for which variances are easy to calculate. Suppose $\mathbb{E} Y=\mu_{Y}$ and $\mathbb{E} Z=\mu_{Z}$. Then

$$
\begin{aligned}
\operatorname{var}(Y+Z) & =\mathbb{E}\left[Y-\mu_{Y}+Z-\mu_{Z}\right]^{2} \\
& =\mathbb{E}\left[\left(Y-\mu_{V}\right)^{2}+2\left(Y-\mu_{Y}\right)\left(Z-\mu_{Z}\right)+\left(Z-\mu_{Z}\right)^{2}\right] \\
& =\operatorname{var}(Y)-\sum_{\mathrm{v}}(Y, Z)+\operatorname{var}(Z)
\end{aligned}
$$

where $\operatorname{cov}(Y, Z)$ denotes the covariance between $Y$ and $Z$ :

$$
\operatorname{cov}(Y, Z):=\mathbb{E}\left[\left(Y-\mu_{Y}\right)\left(Z-\mu_{Z}\right)\right]
$$

Remark. Notice that $\operatorname{cov}(X, X)=\operatorname{var}(X)$. Results about covariances contain results about variances as special cases.

More generally, for constants $a, b, c, d$, and random variables $U, V, Y, Z$,

$$
\begin{aligned}
& \operatorname{cov}(a U+b V, c Y+d Z) \\
& \quad=a c \operatorname{cov}(U, Y)+b c \operatorname{cov}(V, Y)+a d \operatorname{cov}(U, Z)+b d \operatorname{cov}(V, Z)
\end{aligned}
$$

It is easier to see the pattern if we work with the centered random variables $U^{\prime}=U-\mu_{U}, \ldots, Z^{\prime}=Z-\mu_{Z}$. For then the left-hand side becomes

$$
\begin{aligned}
\mathbb{E} & {\left[\left(a U^{\prime}+b V^{\prime}\right)\left(c Y^{\prime}+d Z^{\prime}\right)\right] } \\
& =\mathbb{E}\left[a c U^{\prime} Y^{\prime}+b c V^{\prime} Y^{\prime}+a d U^{\prime} Z^{\prime}+b d V^{\prime} Z^{\prime}\right] \\
& =a c \mathbb{E}\left(U^{\prime} Y^{\prime}\right)+b c \mathbb{E}\left(V^{\prime} Y^{\prime}\right)+a d \mathbb{E}\left(U^{\prime} Z^{\prime}\right)+b d \mathbb{E}\left(V^{\prime} Z^{\prime}\right) .
\end{aligned}
$$

The expected values in the last line correspond to the four covariances.
Sometimes it is easier to subtract off the expected values at the end of the calculation, by means of the formulae $\operatorname{cov}(Y, Z)=\mathbb{E}(Y Z)-(\mathbb{E} Y)(\mathbb{E} Z)$ and, as a particular case, $\operatorname{var}(X)=\mathbb{E}\left(X^{2}\right)-(\mathbb{E} X)^{2}$. Both formulae follow via an expansion of the product:

$$
\begin{aligned}
\operatorname{cov}(Y, Z) & =\mathbb{E}\left(Y Z-\mu_{Y} Z-\mu_{Z} Y+\mu_{Y} \mu_{Z}\right) \\
& =\mathbb{E}(Y Z)-\mu_{Y} \mathbb{E} Z-\mu_{Z} \mathbb{E} Y+\mu_{Y} \mu_{Z} \\
& =\mathbb{E}(Y Z)-\mu_{Y} \mu_{Z} .
\end{aligned}
$$

Rescaled covariances define correlations, a concept that is much abused by those who do not understand probability.

Definition. The correlation between $Y$ and $Z$ is defined as

$$
\operatorname{corr}(Y, Z)=\frac{\operatorname{cov}(Y, Z)}{\sqrt{\operatorname{var}(Y) \operatorname{var}(Z)}}
$$

The random variables $Y$ and $Z$ are said to be uncorrelated if $\operatorname{corr}(Y, Z)=0$.
Remark. Strictly speaking, the variance of a random variable is not well defined unless it has a finite expectation. Similarly, we should not talk about $\operatorname{corr}(Y, Z)$ unless both random variables have well defined variances for which $0<\operatorname{var}(Y)<\infty$ and $0<\operatorname{var}(Z)<\infty$.
$<2>\quad$ Example. When well defined, correlations always lie between +1 and -1 .

Variances for sums of uncorrelated random variables grow more slowly than might be anticipated. If $Y$ and $Z$ are uncorrelated, the covariance term drops out from the expression for the variance of their sum, leaving $\operatorname{var}(Y+Z)=\operatorname{var}(Y)+\operatorname{var}(Z)$. Similarly, if $X_{1}, \ldots, X_{n}$ are random variables for which $\operatorname{cov}\left(X_{i}, X_{j}\right)=0$ for each $i \neq j$ then

$$
\operatorname{var}\left(X_{1}+\cdots+X_{n}\right)=\operatorname{var}\left(X_{1}\right)+\cdots+\operatorname{var}\left(X_{n}\right)
$$

You should check the last assertion by expanding out the quadratic in the variables $X_{i}-\mathbb{E} X_{i}$, observing how all the cross-product terms disappear because of the zero covariances. These facts lead to a useful concentration property.

Example. Concentration of averages around expected value
Zero correlation is often deduced from independence. A pair of random variables $X$ and $Y$ is said to be independent if every event determined by $X$ is independent of every event determined by $Y$. For example, independence implies that events such as $\{X \leq 5\}$ and $\{7 \leq Y \leq 18\}$ are independent, and so on. Independence of the random variables also implies independence of functions of those random variables. For example, $\sin (X)$ would be independent of $e^{Y}$, and so on. For the purposes of Stat241, you should not fret about the definition of independence: Just remember to explain why you regard some pieces of information as irrelevant when you calculate conditional probabilities and conditional expectations.

For example, suppose a random variable $X$ can take values $x_{1}, x_{2}, \ldots$ and that $X$ is independent of another random variable $Y$. Consider the expected value of a product $g(X) h(Y)$, for any functions $g$ and $h$. Calculate by conditioning on the possible values taken by $X$ :

$$
\mathbb{E} g(X) h(Y)=\sum_{i} \mathbb{P}\left\{X=x_{i}\right\} \mathbb{E}\left(g(X) h(Y) \mid X=x_{i}\right)
$$

Given that $X=x_{i}$, we know that $g(X)=g\left(x_{i}\right)$ but we get no help with understanding the behavior of $h(Y)$. Thus, independence implies

$$
\mathbb{E}\left(g(X) h(Y) \mid X=x_{i}\right)=g\left(x_{i}\right) \mathbb{E}\left(h(Y) \mid X=x_{i}\right)=g\left(x_{i}\right) \mathbb{E} h(Y)
$$

Deduce that

$$
\mathbb{E} g(X) h(Y)=\sum_{i} \mathbb{P}\left\{X=x_{i}\right\} g\left(x_{i}\right) \mathbb{E} h(Y)=\mathbb{E} g(X) \mathbb{E} h(Y) .
$$

Put another way, if $X$ and $Y$ are independent random variables

$$
\operatorname{cov}(g(X), h(Y))=\mathbb{E}(g(X) h(Y))-(\mathbb{E} g(X))(\mathbb{E} h(Y))=0
$$

That is, each function of $X$ is uncorrelated with each function of $Y$. In particular, if $X$ and $Y$ are independent then they are uncorrelated. The converse is not usually true: uncorrelated random variables need not be independent.
$<4>\quad$ Example. An example of uncorrelated random variables that are dependent

The concentration phenomenon can also hold for averages of dependent random variables.
$<5>\quad$ Example. Comparison of spread in sample averages for sampling with and without replacement: the Decennial Census.

As with expectations, variances and covariances can also be calculated conditionally on various pieces of information. The conditioning formula in the final Example has the interpretation of a decomposition of "variability" into distinct sources, a precursor to the statistical technique know as the "analysis of variance".
$<6>$ Example. An example to show how variances can sometimes be decomposed into components attributable to difference sources. (Can be skipped.)

## Things to remember.

- $\mathbb{E} g(X) h(Y)=\mathbb{E} g(X) \mathbb{E} h(Y)$ if $X$ and $Y$ are independent random variables
- the initial definitions of variance and covariance, and their expanded forms $\operatorname{cov}(Y, Z)=\mathbb{E}(Y Z)-(\mathbb{E} Y)(\mathbb{E} Z)$ and $\operatorname{var}(X)=\mathbb{E}\left(X^{2}\right)-(\mathbb{E} X)^{2}$
- $\operatorname{var}(a+b X)=b^{2} \operatorname{var}(X)$ and $\operatorname{sd}(a+b X)=|b| \operatorname{sd}(X)$ for constants $a$ and $b$.
- For constants $a, b, c, d$, and random variables $U, V, Y, Z$,

$$
\begin{aligned}
& \operatorname{cov}(a U+b V, c Y+d Z) \\
& \quad=a c \operatorname{cov}(U, Y)+b c \operatorname{cov}(V, Y)+a d \operatorname{cov}(U, Z)+b d \operatorname{cov}(V, Z)
\end{aligned}
$$

- Sampling without replacement gives smaller variances than sampling with replacement.

## Examples for Chapter 4

## Example 1.

The Tchebychev inequality asserts: for a random variable $X$ with expected value $\mu$,

$$
\mathbb{P}\{|X-\mu|>\epsilon\} \leq \operatorname{var}(X) / \epsilon^{2} \quad \text { for each } \epsilon>0
$$

The inequality becomes obvious if we write $F$ for the event $\{|X-\mu|>\epsilon\}$. First note that $\mathbb{I}_{F} \leq|X-\mu|^{2} / \epsilon^{2}$ : when $\mathbb{I}_{F}=0$ the inequality holds for trivial reasons; and when $\mathbb{I}_{F}$ takes the value one, the random variable $|X-\mu|^{2}$ must be larger than $\epsilon^{2}$. It follows that

$$
\mathbb{P}\{|X-\mu|>\epsilon\}=\mathbb{P} F=\mathbb{E} \mathbb{I}_{F} \leq \mathbb{E}|X-\mu|^{2} / \epsilon^{2}
$$

## Example 2.

When well defined, correlations always lies between +1 and -1 .
Suppose

$$
\begin{array}{lll}
\mathbb{E} Y=\mu_{Y} & \text { and } & \operatorname{var}(Y)=\sigma_{Y}^{2} \\
\mathbb{E} Z=\mu_{Y} & \text { and } & \operatorname{var}(Z)=\sigma_{Z}^{2}
\end{array}
$$

Define standardized variables

$$
Y^{\prime}=\frac{Y-\mu_{Y}}{\sigma_{Y}} \quad \text { and } \quad Z^{\prime}=\frac{Z-\mu_{Z}}{\sigma_{Z}} .
$$

Note that $\mathbb{E} Y^{\prime}=\mathbb{E} Z^{\prime}=0$ and $\operatorname{var}\left(Y^{\prime}\right)=\operatorname{var}\left(Z^{\prime}\right)=1$. Also

$$
\operatorname{corr}(Y, Z)=\operatorname{cov}\left(Y^{\prime} Z^{\prime}\right)=\mathbb{E}\left(Y^{\prime} Z^{\prime}\right)
$$

Use the fact that variances are always nonnegative to deduce that

$$
0 \leq \operatorname{var}\left(Y^{\prime}+Z^{\prime}\right)=\operatorname{var}\left(Y^{\prime}\right)+2 \operatorname{cov}\left(Y^{\prime}, Z^{\prime}\right)+\operatorname{var}\left(Z^{\prime}\right)=2+2 \operatorname{cov}\left(Y^{\prime}, Z^{\prime}\right)
$$

which rearranges to $\operatorname{cov}\left(Y^{\prime}, Z^{\prime}\right) \geq-1$. Similarly

$$
0 \leq \operatorname{var}\left(Y^{\prime}-Z^{\prime}\right)=\operatorname{var}\left(Y^{\prime}\right)-2 \operatorname{cov}\left(Y^{\prime}, Z^{\prime}\right)+\operatorname{var}\left(Z^{\prime}\right)=2-2 \operatorname{cov}\left(Y^{\prime}, Z^{\prime}\right)
$$

which rearranges to $\operatorname{cov}\left(Y^{\prime}, Z^{\prime}\right) \leq+1$.

## Example 3.

Suppose $X_{1}, \ldots, X_{n}$ are uncorrelated random variables, each with expected value $\mu$ and variance $\sigma^{2}$. By repeated application of the formulae for the variance of a sum of variables with zero covariances,

$$
\operatorname{var}\left(X_{1}+\cdots+X_{n}\right)=\operatorname{var}\left(X_{1}\right)+\cdots+\operatorname{var}\left(X_{n}\right)=n \sigma^{2} .
$$

Typically the $X_{i}$ would come from repeated independent measurements of some unknown quantity. The random variable $\bar{X}=\left(X_{1}+\cdots+X_{n}\right) / n$ is then called the sample mean.

The variance of the sample mean decreases like $1 / n$,

$$
\operatorname{var}(\bar{X})=(1 / n)^{2} \operatorname{var}\left(X_{1}+\cdots+X_{n}\right)=\sigma^{2} / n .
$$

From the Tchebychev inequality,

$$
\mathbb{P}\{|\bar{X}-\mu|>\epsilon\} \leq\left(\sigma^{2} / n\right) / \epsilon^{2} \quad \text { for each } \epsilon>0 .
$$

In particular, for each positive constant $C$,

$$
\mathbb{P}\{|\bar{X}-\mu|>C \sigma / \sqrt{n}\} \leq 1 / C^{2} .
$$

For example, there is at most a $1 \%$ chance that $\bar{X}$ lies more than $10 \sigma / \sqrt{n}$ away from $\mu$. (A normal approximation will give a much tighter bound.) Note well the dependence on $n$.

## Example 4.

Consider two independent rolls of a fair die. Let $X$ denote the value rolled the first time and $Y$ denote the value rolled the second time. The random variables $X$ and $Y$ are independent, and they have the same distribution. Consequently $\operatorname{cov}(X, Y)=0$, and $\operatorname{var}(X)=\operatorname{var}(Y)$.

The two random variables $X+Y$ and $X-Y$ are uncorrelated:

$$
\begin{aligned}
& \operatorname{cov}(X+Y, X-Y) \\
& \quad=\operatorname{cov}(X, X)+\operatorname{cov}(X,-Y)+\operatorname{cov}(Y, X)+\operatorname{cov}(Y,-Y) \\
& \quad=\operatorname{var}(X)-\operatorname{cov}(X, Y)+\operatorname{cov}(Y, X)-\operatorname{var}(Y) \\
& \quad=0
\end{aligned}
$$

Nevertheless, the sum and difference are not independent. For example,

$$
\mathbb{P}\{X+Y=12\}=\mathbb{P}\{X=6\} \mathbb{P}\{Y=6\}=\frac{1}{36}
$$

but

$$
\mathbb{P}\{X+Y=12 \mid X-Y=5\}=\mathbb{P}\{X+Y=12 \mid X=6, Y=1\}=0 .
$$

## Example 5.

Until quite recently, in the Decennial Census of Housing and Population the Census Bureau would obtain some more detailed about the population via imformation from a more extensive list of questions sent to only a random sample of housing units. For an area like New Haven, about 1 in 6 units would receive the so-called "long form".

For example, one question on the long form asked for the number of rooms in the housing unit. We could imagine the population of all units numbered $1,2, \ldots, N$, with the $i$ th unit containing $y_{i}$ rooms. Complete enumeration would reveal the value of the population average,

$$
\bar{y}=\frac{1}{N}\left(y_{1}+y_{2}+\cdots+y_{N}\right) .
$$

A sample can provide a good estimate of $\bar{y}$ with less work.
Suppose a sample of $n$ housing units are selected from the population without replacement. (For the Decennial Census, $n \approx N / 6$.) The answer from each unit is a random variable that could take each of the values $y_{1}, y_{2}, \ldots, y_{N}$, each with probability $1 / N$.

Remark. It might be better to think of a random variable that takes each of the values $1,2, \ldots, N$ with probability $1 / N$, then take the corresponding number of rooms as the value of the random variable that is recorded. Otherwise we can fall into verbal ambiguities when many of the units have the same number of rooms.

That is, the sample consists of random variables $Y_{1}, Y_{2}, \ldots, Y_{n}$, for each of which

$$
\mathbb{P}\left\{Y_{i}=y_{j}\right\}=\frac{1}{N} \quad \text { for } j=1,2, \ldots, N
$$

Notice that

$$
\mathbb{E} Y_{i}=\frac{1}{N} \sum_{j=1}^{N} y_{j}=\bar{y}
$$

and consequently, the sample average $\bar{Y}=\left(Y_{1}+\cdots+Y_{n}\right) / n$ also has expected value $\bar{y}$. Notice also that each $Y_{i}$ has the same variance,

$$
\operatorname{var}\left(Y_{i}\right)=\frac{1}{N} \sum_{j=1}^{N}\left(y_{j}-\bar{y}\right)^{2},
$$

a quantity that I will denote by $\sigma^{2}$.
If the sample is taken without replacement-which, of course, the Census Bureau had to do, if only to avoid media ridicule - the random variables are
dependent. For example, in the extreme case where $n=N$, we would necessarily have

$$
Y_{1}+Y_{2}+\cdots+Y_{N}=y_{1}+y_{2}+\cdots+y_{N}
$$

so that $Y_{N}$ would be a function of the other $Y_{i}$ 's, a most extreme form of dependence. Even if $n<N$, there is still some dependence, as you will soon see.

Sampling with replacement would be mathematically simpler, for then the random variables $Y_{i}$ would be independent, and, as in Example $<3>$, we would have $\operatorname{var}(\bar{Y})=\sigma^{2} / n$. With replacement, it is possible that the same unit might be sampled more than once, especially if the sample size is an appreciable fraction of the population size. There is also some inefficiciency in sampling with replacement, as shown by a calculation of variance for sampling without replacement:

$$
\begin{aligned}
\operatorname{var}(\bar{Y}) & =\mathbb{E}(\bar{Y}-\bar{y})^{2} \\
& =\mathbb{E}\left(\frac{1}{n} \sum_{i=1}^{n}\left(Y_{i}-\bar{y}\right)\right)^{2} \\
& =\frac{1}{n^{2}} \mathbb{E}\left(\sum_{i=1}^{n}\left(Y_{i}-\bar{y}\right)^{2}+2 \sum_{1 \leq i<j \leq n}\left(Y_{i}-\bar{y}\right)\left(Y_{j}-\bar{y}\right)\right) \\
& =\frac{1}{n^{2}}\left(\sum_{i=1}^{n} \mathbb{E}\left(Y_{i}-\bar{y}\right)^{2}+2 \sum_{1 \leq i<j \leq n} \mathbb{E}\left(\left(Y_{i}-\bar{y}\right)\left(Y_{j}-\bar{y}\right)\right)\right) \\
& =\frac{1}{n^{2}}\left(\sum_{i=1}^{n} \operatorname{var}\left(Y_{i}\right)+\sum_{1 \leq i \neq j \leq n} \operatorname{cov}\left(Y_{i}, Y_{j}\right)\right)
\end{aligned}
$$

What formula did I just rederive?

There are $n$ variance terms and $n(n-1)$ covariance terms. We know that each $Y_{i}$ has variance $\sigma^{2}$, regardless of the dependence between the variables. The effect of the dependence shows up in the covariance terms. By symmetry, $\operatorname{cov}\left(Y_{i}, Y_{j}\right)$ is the same for each pair $i<j$, a value that I will denote by $c$. Thus, for sampling without replacement,

$$
\begin{equation*}
\operatorname{var}(\bar{Y})=\frac{1}{n^{2}}\left(n \sigma^{2}+n(n-1) c\right)=\frac{\sigma^{2}}{n}+\frac{(n-1) c}{n} \tag{*}
\end{equation*}
$$

We can calculate $c$ directly, from the fact that the pair $\left(Y_{1}, Y_{2}\right)$ takes each of $N(N-1)$ pairs of values $\left(y_{i}, y_{j}\right)$ with equal probability. Thus

$$
c=\operatorname{cov}\left(Y_{1}, Y_{2}\right)=\frac{1}{N(N-1)} \sum_{i \neq j}\left(y_{i}-\bar{y}\right)\left(y_{j}-\bar{y}\right) .
$$

If we added the "diagonal" terms $\left(y_{i}-\bar{y}\right)^{2}$ to the sum we would have the expansion for the product

$$
\sum_{i=1}^{N}\left(y_{i}-\bar{y}\right) \sum_{j=1}^{N}\left(y_{j}-\bar{y}\right),
$$

which equals zero because $N \bar{y}=\sum_{i=1}^{N} y_{i}$. The expression for the covariance simplifies to

$$
c=\operatorname{cov}\left(Y_{1}, Y_{2}\right)=\frac{1}{N(N-1)}\left(0^{2}-\sum_{i=1}^{N}\left(y_{i}-\bar{y}\right)^{2}\right)=-\frac{\sigma^{2}}{N-1} .
$$

Substitution in formula (*) then gives

$$
\operatorname{var}(\bar{Y})=\frac{\sigma^{2}}{n}\left(1-\frac{n-1}{N-1}\right)=\frac{\sigma^{2}}{n} \frac{N-n}{N-1} .
$$

Compare with the $\sigma^{2} / n$ for $\operatorname{var}(\bar{Y})$ under sampling with replacement. The correction factor $(N-n) /(N-1)$ is close to 1 if the sample size $n$ is small compared with the population size $N$, but it can decrease the variance of $\bar{Y}$ appreciably if $n / N$ is not small. For example, if $n \approx N / 6$ (as with the Census long form) the correction factor is approximately $5 / 6$.

If $n=N$, the correction factor is zero. That is, $\operatorname{var}(\bar{Y})=0$ if the whole population is sampled. Indeed, when $n=N$ we know that $\bar{Y}$ equals the population mean, $\bar{y}$, a constant. A random variable that always takes the same constant value has zero variance. Thus the right-hand side of $(*)$ must reduce to zero when we put $n=N$, which gives a quick method for establishing the equality $c=-\sigma^{2} /(N-1)$, without all the messing around with sums of products and products of sums.

## Example 6.

Consider a two stage method for generating a random variable $Z$. Suppose we have $k$ different random variables $Y_{1}, \ldots, Y_{k}$, with $\mathbb{E} Y_{i}=\mu_{i}$ and $\operatorname{var}\left(Y_{i}\right)=$ $\sigma_{i}^{2}$. Suppose also that we have a random method for selecting which variable to choose: a random variable $X$ that is independent of all the $Y_{i}$ 's, with $\mathbb{P}\{X=i\}=p_{i}$ for $i=1,2, \ldots, k$, where $p_{1}+p_{2}+\cdots+p_{k}=1$. If $X$ takes the value $i$, define $Z$ to equal $Y_{i}$.

The variability in $Z$ is due to two effects: the variability of each $Y_{i}$; and the variability of $X$. Conditional on $X=i$, we have $Z$ equal to $Y_{i}$, and

$$
\begin{aligned}
\mathbb{E}(Z \mid X=i) & =\mathbb{E}\left(Y_{i}\right)=\mu_{i} \\
\operatorname{var}(Z \mid X=i) & =\mathbb{E}\left(\left(Z-\mu_{i}\right)^{2} \mid X=i\right)=\operatorname{var}\left(Y_{i}\right)=\sigma_{i}^{2} .
\end{aligned}
$$

From the first formula we get

$$
\mathbb{E} Z=\sum_{i} \mathbb{P}\{X=i\} \mathbb{E}(Z \mid X=i)=\sum_{i} p_{i} \mu_{i}
$$

a weighted average of the $\mu_{i}$ 's that I will denote by $\bar{\mu}$. A similar conditioning exercise gives

$$
\operatorname{var}(Z)=\mathbb{E}(Z-\bar{\mu})^{2}=\sum_{i} p_{i} \mathbb{E}\left((Z-\bar{\mu})^{2} \mid X=i\right)
$$

If we could replace the $\bar{\mu}$ in the $i$ th summand by $\mu_{i}$, the sum would become a weighted average of conditional variances. To achieve such an effect, rewrite $(Z-\bar{\mu})^{2}$ as

$$
\left(Z-\mu_{i}+\mu_{i}-\bar{\mu}\right)^{2}=\left(Z-\mu_{i}\right)^{2}+2\left(\mu_{i}-\bar{\mu}\right)\left(Z_{i}-\mu_{i}\right)+\left(\mu_{i}-\bar{\mu}\right)^{2} .
$$

Taking conditional expectations, we then get

$$
\begin{aligned}
& \mathbb{E}\left((Z-\bar{\mu})^{2} \mid X=i\right) \\
& \quad=\mathbb{E}\left(\left(Z-\bar{\mu}_{i}\right)^{2} \mid X=i\right)+2\left(\mu_{i}-\bar{\mu}\right) \mathbb{E}\left(Z-\mu_{i} \mid X=i\right)+\left(\mu_{i}-\bar{\mu}\right)^{2} .
\end{aligned}
$$

On the right-hand side, the first term equals $\sigma_{i}^{2}$, and the middle term disappears because $\mathbb{E}(Z \mid X=i)=\mu_{i}$. With those simplifications, the expression for the variance becomes

$$
\operatorname{var}(Z)=\sum_{i} p_{i} \sigma_{i}^{2}+\sum_{i} p_{i}\left(\mu_{i}-\bar{\mu}\right)^{2}
$$

If we think of each $Y_{i}$ as coming from a separate "population", the first sum represents the component of variability within the populations, and the second sum represents the variability between the populations.

The formula is sometimes written symbolically as

$$
\operatorname{var}(Z)=\mathbb{E}(\operatorname{var}(Z \mid X))+\operatorname{var}(\mathbb{E}(Z \mid X))
$$

where $E(Z \mid X)$ denotes the random variable that takes the value $\mu_{i}$ when $X$ takes the value $i$, and $\operatorname{var}(Z \mid X)$ denotes the random variable that takes the value $\sigma_{i}^{2}$ when $X$ takes the value $i$.

## Chapter 5

## Normal approximation to the Binomial

In 1733, Abraham de Moivre presented an approximation to the Binomial distribution. He later (de Moivre, 1756, page 242) appended the derivation of his approximation to the solution of a problem asking for the calculation of an expected value for a particular game. He posed the rhetorical question of how we might show that experimental proportions should be close to their expected values:

From this it follows, that if after taking a great number of Experiments, it should be perceived that the happenings and failings have been nearly in a certain proportion, such as of 2 to 1, it may safely be concluded that the Probabilities of happening or failing at any one time assigned will be very near in that proportion, and that the greater the number of Experiments has been, so much nearer the Truth will the conjectures be that are derived from them.

But suppose it should be said, that notwithstanding the reasonableness of building Conjectures upon Observations, still considering the great Power of Chance, Events might at long run fall out in a different proportion from the real Bent which they have to happen one way or the other; and that supposing for Instance that an Event might as easily happen as not happen, whether after three thousand Experiments it may not be possible it should have happened two thousand times and failed a thousand; and that therefore the Odds against so great a variation from Equality should be assigned, whereby the Mind would be the better disposed in the Conclusions derived from the Experiments.

In answer to this, I'll take the liberty to say, that this is the hardest Problem that can be proposed on the Subject of Chance, for which reason I have reserved it for the last, but I hope to be forgiven if my Solution is not fitted to the capacity of all Readers; however I shall derive from it some Conclusions that may be of use to every body: in order thereto, I shall here translate a Paper of mine which was printed November 12, 1733, and communicated to some Friends, but never yet made public, reserving to myself the right of enlarging my own Thoughts, as occasion shall require.

Novemb. 12, 1733

De Moivre then stated and proved what is now known as the normal approximation to the Binomial distribution. The approximation itself has subsequently been generalized to give normal approximations for many other distributions. Nevertheless, de Moivre's elegant method of proof is still
worth understanding. This Chapter will explain de Moivre's approximation, using modern notation.

## A Method of approximating the Sum of the Terms of the Binomial $\overline{a+b}{ }^{n}$ expanded into a Series, from whence are deduced some practical Rules to estimate the Degree of Assent which is to be given to Experiments.

Altho' the Solution of problems of Chance often requires that several Terms of the Binomial $\overline{a+b}{ }^{n}$ be added together, nevertheless in very high Powers the thing appears so laborious, and of so great difficulty, that few people have undertaken that Task; for besides James and Nicolas Bernouilli, two great Mathematicians, I know of no body that has attempted it; in which, tho' they have shown very great skill, and have the praise that is due to their Industry, yet some things were further required; for what they have done is not so much an Approximation as the determining very wide limits, within which they demonstrated that the Sum of the Terms was contained. Now the method...

Suppose $X_{n}$ has a $\operatorname{Bin}(n, p)$ distribution. That is,
$b_{n}(k):=\mathbb{P}\left\{X_{n}=k\right\}=\binom{n}{k} p^{k} q^{n-k} \quad$ for $k=0,1, \ldots, n$, where $q=1-p$,
Recall that we can think of $X_{n}$ as a sum of independent random variables $Y_{1}+\cdots+Y_{n}$ with $\mathbb{P}\left\{Y_{i}=1\right\}=p$ and $\mathbb{P}\left\{Y_{i}=0\right\}=q$. From this representation it follows that

$$
\begin{aligned}
\mathbb{E} X_{n} & =\sum_{i} \mathbb{E} Y_{i}=n \mathbb{E} Y_{1}=n p \\
\operatorname{var}\left(X_{n}\right) & =\sum_{i} \operatorname{var}\left(Y_{i}\right)=n \operatorname{var}\left(Y_{1}\right)=n p q
\end{aligned}
$$

Recall that Tchebychev's inequality suggests the distribution should be clustered around $n p$, with a spread determined by the standard deviation, $\sigma_{n}:=\sqrt{n p q}$.

What does the Binomial distribution look like? The plots in the next display, for the $\operatorname{Bin}(n, 0.4)$ distribution with $n=20,50,100,150,200$, are typical. Each plot on the left shows bars of height $b_{n}(k)$ and width 1 , centered at $k$. The maxima occur near $n \times 0.4$ for each plot. As $n$ increases,
the spread also increases, reflecting the increase in the standard deviations $\sigma_{n}=\sqrt{n p q}$ for $p=0.4$. Each of the shaded regions on the left has area

$$
\sum_{k=0}^{n} b_{n}(k)=1 \quad \text { for various } n .
$$

The plots on the right show represent the distributions of the standardized random variables $Z_{n}=\left(X_{n}-n p\right) / \sigma_{n}$. The location and scaling effects of the increasing expected values and standard deviations (with $p=0.4$ and various $n$ ) are now removed. Each plot is shifted to bring the location of the maximum close to 0 and the horizontal scale is multiplied by a factor $1 / \sigma_{n}$. A bar of height $\sigma_{n} \times b_{n}(k)$ with width $1 / \sigma_{n}$ is now centered at $(k-n p) / \sigma_{n}$. The plots all have similar shapes. Each shaded region still has area 1.

Notice how the plots on the right settle down to a symmetric 'bellshaped' curve. The shape of the "standardized" Binomial quickly stablizes as $n$ increases.

You can understand this effect by looking at the ratio of successive terms:

$$
\begin{aligned}
b_{n}(k) & / b_{n}(k-1) \\
& =\left(\frac{n!}{k!(n-k)!} p^{k} q^{n-k}\right) /\left(\frac{n!}{(k-1)!(n-k+1)!} p^{k-1} q^{n-k+1}\right) \\
& =\frac{(n-k+1) p}{k q} \quad \text { for } k=1,2, \ldots, n .
\end{aligned}
$$

As a consequence, $b_{n}(k) \geq b_{n}(k-1)$ if and only if $(n-k+1) p \geq k q$, that is, iff $(n+1) p \geq k$. For fixed $n$, the probability $b_{n}(k)$ achieves its largest value at $k_{\max }=\lfloor(n+1) p\rfloor \approx n p$. In the following I will ignore the difference between $k_{\max }$ and $n p$. The probabilities $b_{n}(k)$ increase with $k$ for $k \leq k_{\max }$ then decrease for $k>k_{\max }$.

That explains why each plot on the left has a peak near $n p$.
Now for the shape. At least for $k=k_{\max }+i$ near $k_{\max }$ we get a good approximation for the logarithm of the ratio of successive terms using the Taylor approximation

$$
\log (1+x) \approx x \quad \text { for } x \text { near } 0
$$

Indeed,

$$
\begin{aligned}
b\left(k_{\max }\right. & +i) / b\left(k_{\max }+i-1\right) \\
& =\frac{\left(n-k_{\max }-i+1\right) p}{\left(k_{\max }+i\right) q} \\
& \approx \frac{(n q-i) p}{(n p+i) q} \\
& =\frac{1-i /(n q)}{1+i /(n p)} \quad \text { after dividing through by } n p q .
\end{aligned}
$$

The logarithm of the last ratio equals

$$
\log \left(1-\frac{i}{n q}\right)-\log \left(1+\frac{i}{n p}\right) \approx-\frac{i}{n q}-\frac{i}{n p}=-\frac{i}{n p q}
$$

By taking a product of successive ratios we get an approximation for the logarithm of the ratio of the individual Binomial probabilities to their largest term. On a log scale the calculation is even simpler. For example, if

$$
\begin{aligned}
& m \geq 1 \text { and } k_{\max }+m \leq n \\
& \qquad \begin{aligned}
\log & \frac{b\left(k_{\max }+m\right)}{b\left(k_{\max }\right)} \\
& =\log \left(\frac{b\left(k_{\max }+1\right)}{b\left(k_{\max }\right)} \times \frac{b\left(k_{\max }+2\right)}{b\left(k_{\max }+1\right)} \times \cdots \times \frac{b\left(k_{\max }+m\right)}{b\left(k_{\max }+m-1\right)}\right) \\
& =\log \frac{b\left(k_{\max }+1\right)}{b\left(k_{\max }\right)}+\log \frac{b\left(k_{\max }+2\right)}{b\left(k_{\max }+1\right)}+\cdots+\log \frac{b\left(k_{\max }+m\right)}{b\left(k_{\max }+m-1\right)} \\
& \approx \frac{-1-2-\cdots-m}{n p q} \\
& \approx-\frac{1}{2} \frac{m^{2}}{n p q}
\end{aligned}
\end{aligned}
$$

The last line used the fact that

$$
1+2+3+\cdots+m=\frac{1}{2} m(m+1) \approx \frac{1}{2} m^{2}
$$

In summary,

$$
\mathbb{P}\left\{X=k_{\max }+m\right\} \approx b\left(k_{\max }\right) \exp \left(-\frac{m^{2}}{2 n p q}\right) \quad \text { for } m \text { not too large. }
$$

An analogous approximation holds for $0 \leq k_{\max }+m \leq k_{\max }$.
Using the fact that the probabilities sum to 1 , for $p=1 / 2$ de Moivre was able to show that the $b\left(k_{\max }\right)$ should decrease like $2 /(B \sqrt{n})$, for a constant $B$ that he was initially only able to express as an infinite sum. Referring to his calculation of the ratio of the maximum term in the expansion of $(1+1)^{n}$ to the sum, $2^{n}$, he wrote (de Moivre, 1756, page 244)

When I first began that inquiry, I contented myself to determine at large the Value of $B$, which was done by the addition of some Terms of the above-written Series; but as I perceived that it converged but slowly, and seeing at the same time that what I had done answered my purpose tolerably well, I desisted from proceeding further till my worthy and learned Friend Mr. James Stirling, who had applied himself after me to that inquiry, found that the Quantity $B$ did denote the Square-root of the Circumference of a Circle whose Radius is Unity, so that if that Circumference be called c, the Ratio of the middle Term to the Sum of all the Terms will be expressed by $2 \sqrt{n} c$.

In modern notation, the vital fact discovered by the learned Mr. James Stirling asserts that

$$
n!\approx \sqrt{2 \pi} n^{n+1 / 2} e^{-n} \quad \text { for } n=1,2, \ldots
$$

in the sense that the ratio of both sides tends to 1 (very rapidly) as $n$ goes to infinity. See Feller (1968, pp52-53) for an elegant, modern derivation of the Stirling formula.

Consequently, for $k \approx n p$,

$$
\begin{aligned}
b_{n}(k) & =\frac{n!}{k!(n-k)!} p^{k} q^{n-k} \\
& \approx \frac{1}{\sqrt{2 \pi}} \frac{n^{n+1 / 2}}{(n p)^{n p+1 / 2}(n q)^{n q+1 / 2}} p^{n p} q^{n q} \\
& =\frac{1}{\sqrt{2 \pi n p q}} .
\end{aligned}
$$

De Moivre's approximation becomes

$$
\mathbb{P}\left\{X_{n}=k_{\max }+m\right\} \approx \frac{1}{\sqrt{2 \pi n p q}} \exp \left(-\frac{m^{2}}{2 n p q}\right),
$$

or, substituting $n p$ for $k_{\max }$ and writing $k$ for $k_{\max }+m$,

$$
\mathbb{P}\left\{X_{n}=k\right\} \approx \frac{1}{\sqrt{2 \pi n p q}} \exp \left(-\frac{(k-n p)^{2}}{2 n p q}\right)=\frac{1}{\sqrt{2 \pi} \sigma_{n}} \exp \left(-\frac{(k-n p)^{2}}{2 \sigma_{n}^{2}}\right) .
$$

That is, $\mathbb{P}\left\{X_{n}=k\right\}$ is approximately equal to the area under the smooth curve

$$
f(x)=\frac{1}{\sqrt{2 \pi} \sigma_{n}} \exp \left(-\frac{(x-n p)^{2}}{2 \sigma_{n}^{2}}\right),
$$

for the interval $k-1 / 2 \leq x \leq k+1 / 2$. (The length of the interval is 1 , so it does not appear in the previous display.)

Similarly, for each pair of integers with $0 \leq a<b \leq n$,

$$
\mathbb{P}\left\{a \leq X_{n} \leq b\right\}=\sum_{k=a}^{b} b_{n}(k) \approx \sum_{k=a}^{b} \int_{k-1 / 2}^{k+1 / 2} f(x) d x=\int_{a-1 / 2}^{b+1 / 2} f(x) d x
$$

A change of variables, $y=(x-n p) / \sigma_{n}$, simplifies the last integral to

$$
\frac{1}{\sqrt{2 \pi}} \int_{\alpha}^{\beta} e^{-y^{2} / 2} d y \quad \text { where } \alpha=\frac{a-n p-1 / 2}{\sigma_{n}} \text { and } \beta=\frac{-n p+1 / 2}{\sigma_{n}} \text {. }
$$

Remark. It usually makes little difference to the approximation if we omit the $\pm 1 / 2$ terms from the definitions of $\alpha$ and $\beta$.

How does one actually perform a normal approximation? Back in the olden days, I would have interpolated from a table of values for the function

$$
\Phi(x):=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{x} e^{-y^{2} / 2} d y
$$

which was found in most statistics texts. For example, if $X$ has a $\operatorname{Bin}(100,1 / 2)$ distribution,

$$
\begin{aligned}
\mathbb{P}\{45 \leq X \leq 55\} & \approx \Phi\left(\frac{55.5-50}{5}\right)-\Phi\left(\frac{44.5-50}{5}\right) \\
& \approx 0.8643-0.1356=0.7287
\end{aligned}
$$

These days, I would just calculate in R:

$$
\begin{aligned}
& >\text { pnorm(55.5, mean }=50, \text { sd }=5)- \text { pnorm }(44.5 \text {, mean }=50, \text { sd }=5) \\
& \text { [1] } 0.7286679
\end{aligned}
$$

or use another very accurate, built-in approximation:

```
> pbinom(55,size \(=100\), prob \(=0.5\) ) \(-\operatorname{pbinom}(44\), size \(=100\), prob \(=0.5)\)
[1] 0.728747
```

## 

At this point, the integral in the definition of $\Phi(x)$ is merely a reflection of the Calculus trick of approximating a sum by an integral. Probabilists have taken a leap into abstraction by regarding $\Phi$, or its derivative $\phi(y):=$ $\exp \left(-y^{2} / 2\right) / \sqrt{2 \pi}$, as a way to define a probability distribution
$<1>\quad$ Definition. A random variable $Y$ is said to have a continuous distribution (on $\mathbb{R}$ ) with density function $f(\cdot)$ if

$$
\mathbb{P}\{a \leq Y \leq b\}=\int_{a}^{b} f(y) d y \quad \text { for all intervals }[a, b] \subseteq \mathbb{R}
$$

Equivalently, for each subset $A$ of the real line,

$$
\mathbb{P}\{Y \in A\}=\int_{A} f(y) d y=\int_{-\infty}^{\infty} \mathbb{I}\{y \in A\} f(y) d y
$$

Notice that $f$ should be a nonnegative function, for otherwise it might get awkward when calculating $\mathbb{P}\{Y \in A\}$ for the set $A=\{y \in \mathbb{R}: f(y)<0\}$ :

$$
0 \leq \mathbb{P}\{Y \in A\}=\int_{A} f(y) d y \leq 0
$$

Remark. By putting $A$ equal to $\mathbb{R}$ we get

$$
1=\mathbb{P}\{-\infty<Y<+\infty\}=\int_{-\infty}^{\infty} f(y) d y
$$

That is, the integral of a density function over the whole real line equals one.

I prefer to think of densities as being defined on the whole real line, with values outside the range of the random variable being handled by setting the density function equal to zero in appropriate places. If a range of integration is not indicated explicitly, it can then always be understood as $-\infty$ to $\infty$, with the zero density killing off unwanted contributions.

Distributions defined by densities have both similarities with and differences from the sort of distributions I have been considering up to this point in Stat 241/541. All the distributions before now were discrete. They were described by a (countable) discrete set of possible values $\left\{x_{i}: i=1,2, \ldots\right\}$ that could be taken by a random variable $X$ and the probabilities with which $X$ took those values:

$$
\mathbb{P}\left\{X=x_{i}\right\}=p_{i} \quad \text { for } i=1,2, \ldots
$$

For any subset $A$ of the real line

$$
\mathbb{P}\{X \in A\}=\sum_{i} \mathbb{I}_{\left\{x_{i} \in A\right\}} \mathbb{P}\left\{X=x_{i}\right\}=\sum_{i} \mathbb{I}_{\left\{x_{i} \in A\right\}} p_{i}
$$

Expectations, variances, and things like $\mathbb{P} g(X)$ could all be calculated by conditioning on the possible values for $X$.

For a random variable $X$ with a continuous distribution defined by a density $f$, we have

$$
\mathbb{P}\{X=x\}=\int_{x}^{x} f(y) d y=0
$$

for every $x \in \mathbb{R}$. We cannot hope to calculate a probability by adding up (an uncountable set of) zeros. Instead we must pass to a limit and replace sums by integrals.

As you will see in the next Chapter, expected values, variances and things like $\mathbb{P} g(X)$ can all be recovered as integrals after a passage to a limit when a random variable $X$ has a continuous distribution.

Appendix: The mysterious $\sqrt{2 \pi}$
Notice that, for the $\operatorname{Binomial}(n, 1 / 2)$ distribution with $n$ very large,

$$
\begin{aligned}
1 & =\mathbb{P}\left\{0 \leq X_{n} \leq n\right\} \\
& =\mathbb{P}\left\{-\sqrt{n} \leq \frac{X_{n}-n / 2}{\sqrt{n / 4}} \leq \sqrt{n}\right\} \\
& \approx \Phi(\sqrt{n})-\Phi(-\sqrt{n}) \approx \frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{+\infty} e^{-y^{2} / 2} d y .
\end{aligned}
$$

In fact, the constant $C:=\int_{-\infty}^{\infty} \exp \left(-x^{2} / 2\right) d x$ is exactly equal to $\sqrt{2 \pi}$, as I now explain.

Equivalently, the constant $C^{2}=\iint \exp \left(-\left(x^{2}+y^{2}\right) / 2\right) d x d y$ equal to $2 \pi$. (Here, and subsequently, the double integral runs over the whole plane.) We can evaluate this double integral by using a small Calculus trick.

Using the fact that

$$
\int_{0}^{\infty} \mathbb{I}\{r \leq z\} e^{-z} d z=e^{-r} \quad \text { for } r>0
$$

we may rewrite $C^{2}$ as a triple integral: replace $r$ by $\left(x^{2}+y^{2}\right) / 2$, then substitute into the double integral to get

$$
\begin{aligned}
C^{2} & =\iint\left(\int_{0}^{\infty} \mathbb{I}\left\{x^{2}+y^{2} \leq 2 z\right\} e^{-z} d z\right) d x d y \\
& =\int_{0}^{\infty}\left(\iint \mathbb{I}\left\{x^{2}+y^{2} \leq 2 z\right\} d x d y\right) e^{-z} d z
\end{aligned}
$$

With the change in the order of integration, the double integral is now calculating the area of a circle centered at the origin and with radius $\sqrt{2 z}$. The triple integral reduces to

$$
\int_{0}^{\infty} \pi(\sqrt{2 z})^{2} e^{-z} d z=\int_{0}^{\infty} \pi 2 z e^{-z} d z=2 \pi
$$

That is, $C=\sqrt{2 \pi}$, as asserted.

## Chapter 6

## Continuous Distributions

In Chapter 5 you met your first example of a continuous distribution, the normal. Recall the general definition.

Definition. A random variable $X$ is said to have a continuous distribution (on $\mathbb{R}$ ) with density function $f(\cdot)$ if
(i) $f$ is a nonnegative function on the real line for which $\int_{-\infty}^{+\infty} f(x) d x=1$
(ii) for each subset $A$ of the real line,

$$
\mathbb{P}\{X \in A\}=\int_{A} f(x) d x=\int_{-\infty}^{\infty} \mathbb{I}\{x \in A\} f(x) d y
$$

As a special case of (ii),

$$
\mathbb{P}\{a \leq X \leq b\}=\int_{a}^{b} f(x) d x \quad \text { for all intervals }[a, b] \subseteq \mathbb{R} .
$$

For the normal approximation to the $\operatorname{Bin}(n, p)$ the density was

$$
f(x)=\frac{1}{\sigma \sqrt{2 \pi}} \exp \left(\frac{-(x-\mu)^{2}}{2 \sigma^{2}}\right) \quad \text { for }-\infty<x<\infty
$$

with $\mu=n p$ and $\sigma^{2}=n p q$.
Remark. Later this distribution will be denoted by $N\left(\mu, \sigma^{2}\right)$, the normal distribution with parameters $\mu$ and $\sigma^{2}$. As you will soon learn, the distribution has expected value $\mu$ and variance $\sigma^{2}$.

Notice that a change of variable $y=(x-\mu) / \sigma$ gives

$$
\int_{-\infty}^{\infty} f(x) d x=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{\infty} e^{-y^{2} / 2} d y
$$

which (see Chapter 5) equals 1 .
The simplest example of a continuous distribution is the Uniform $[0,1]$, the distribution of a random variable $U$ that takes values in the interval $[0,1]$, with

$$
\mathbb{P}\{a \leq U \leq b\}=b-a \quad \text { for all } 0 \leq a \leq b \leq 1
$$

Equivalently,

$$
\mathbb{P}\{a \leq U \leq b\}=\int_{a}^{b} f(x) d x \quad \text { for all real } a, b
$$

where

$$
f(x)= \begin{cases}1 & \text { if } 0<x<1 \\ 0 & \text { otherwise }\end{cases}
$$

I will use the Uniform to illustrate several general facts about continuous distributions.

Remark. Of course, to actually simulate a Uniform $[0,1]$ distribution on a computer one would work with a discrete approximation. For example, if numbers were specified to only 7 decimal places, one would be approximating Uniform $[0,1]$ by a discrete distribution placing probabilities of about $10^{-7}$ on a fine grid of about $10^{7}$ equi-spaced points in the interval. You might think of the Uniform $[0,1]$ as a convenient idealization of the discrete approximation.

Be careful not to confuse the density $f(x)$ with the probabilities $p(y)=\mathbb{P}\{Y=y\}$ used to specify discrete distributions, that is, distributions for random variables that can take on only a finite or countably infinite set of different values. The $\operatorname{Bin}(n, p)$ and the geometric $(p)$ are both discrete distributions. Continuous distributions smear the probability out over a continuous range of values. In particular, if $X$ has a continuous distribution with density $f$ then

$$
\mathbb{P}\{X=t\}=\int_{t}^{t} f(x) d x=0 \quad \text { for each fixed } t
$$

The value $f(x)$ does not represent a probability. Instead, the values taken by the density function could be thought of as constants of proportionality. At least at points where the density function $f$ is continuous and when $\delta$ is small,

$$
\mathbb{P}\{t \leq X \leq t+\delta\}=\int_{t}^{t+\delta} f(x) d y=f(t) \delta+\text { terms of order } o(\delta)
$$

Remark. Remember that $g(\delta)=o(\delta)$ means that $g(\delta) / \delta \rightarrow 0$ as $\delta \rightarrow 0$.
Equivalently,

$$
\lim _{\delta \rightarrow 0} \frac{1}{\delta} \mathbb{P}\{t \leq X \leq t+\delta\}=f(t)
$$

The density function must be non-negative, for otherwise some tiny interval would receive a negative probability.

Some texts define the density as the derivative of the cumulative distribution function

$$
F(t)=\mathbb{P}\{-\infty<X \leq t\} \quad \text { for }-\infty<t<\infty
$$

That is,

$$
f(t)=\lim _{\delta \rightarrow 0} \frac{1}{\delta}(F(t+\delta)-F(t))
$$

This approach works because

$$
\begin{aligned}
\mathbb{P}\{t \leq & =X \leq t+\delta\} \\
& =\mathbb{P}\{X \leq t+\delta\}-\mathbb{P}\{X<t\} \\
& =F(t+\delta)-F(t) \quad \text { because } \mathbb{P}\{X=t\}=0 .
\end{aligned}
$$

When we are trying to determine a density function, the trick is to work with very small intervals, so that higher order terms in the lengths of the intervals can be ignored. (More formally, the errors in approximation tend to zero as the intervals shrink.)
$<1>\quad$ Example. Functions of a random variable with a continuous distribution.
I recommend that you remember the method used in the previous Example, rather than trying to memorize the result for various special cases. In each particular application, rederive. That way, you will be less likely to miss multiple contributions to a density.

Calculations with continuous distributions typically involve integrals or derivatives where discrete distribution involve sums or probabilities attached to individual points. The formulae developed in previous chapters for expectations and variances of random variables have analogs for continuous distributions.
$<2>\quad$ Example. Expectation of a random variable with a continuous distribution: if the distribution of $X$ has density $f$ then $\mathbb{E} H(X)=\int_{-\infty}^{+\infty} H(x) f(x) d x$.

You should be very careful not to confuse the formulae for expectations in the discrete and continuous cases. Think again if you find yourself integrating probabilities or summing expressions involving probability densities.
$<3>\quad$ Example. Expected value and variance for the $N\left(\mu, \sigma^{2}\right)$.

Calculations for continuous distributions are often simpler than analogous calculations for discrete distributions because we are able to ignore some pesky cases.
<4>
$<5>$
Example. The distribution of the order statistics from the uniform distribution.
The distribution from the previous Example is a member of a family whose name is derived from the beta function, defined by

$$
B(\alpha, \beta):=\int_{0}^{1} t^{\alpha-1}(1-t)^{\beta-1} d t \quad \text { for } \alpha>0, \beta>0
$$

The equality

$$
\int_{0}^{1} t^{k-1}(1-t)^{n-k} d t=\frac{(k-1)!(n-k)!}{n!}
$$

noted at the end of the Example, gives the value for $B(k, n-k+1)$.
In general, if we divide $t^{\alpha-1}(1-t)^{\beta-1}$ by $B(\alpha, \beta)$ we get a candidate for a density function: non-negative and integrating to 1 .

Definition. For $\alpha>0$ and $\beta>0$ the $\operatorname{Beta}(\alpha, \beta)$ distribution is defined by the density function

$$
\frac{x^{\alpha-1}(1-x)^{\beta-1}}{B(\alpha, \beta)} \quad \text { for } 0<x<1 \text {. }
$$

The density is zero outside $(0,1)$.
As you just saw in Example $<5>$, the $k$ th order statistic from a sample of $n$ independently generated random variables with Uniform $[0,1]$ distributions has a $\operatorname{Beta}(k, n-k+1)$ distribution.

The function beta() in R calculates the value of the beta function:

```
> beta(5.5,2.7)
[1] 0.01069162
> ?beta # get help for the beta() function
```

Also, there is a set of R functions that gives useful results for the beta density. For example, the pictures on the next page could be drawn by a series of R commands like:

```
>jj=(1:1000)/1000
plot(jj,dbeta(jj,2,3),type="l")
```

The functions dbeta() calculates the values of the beta density at a fine grid of points. The plot() function is called with the option of joining the points by a smooth curve.

Beta densities: $\mathrm{t}^{\alpha-1}(1-\mathrm{t})^{\beta-1} / \mathrm{B}(\alpha, \beta)$ for $0<\mathrm{t}<1$ and vertical range $(0,5)$

There is an interesting exact relationship between the tails of the beta and Binomial distributions.

Example. Binomial tail probabilities from beta distributions.

## Things to remember.

- The density function $f(\cdot)$ gives the constants of proportionality, and not probabilities: $f(x)$ is not the same as $\mathbb{P}\{X=0\}$, which is zero for every $x$ if $X$ has a continuous distribution.
- A density function, $f$, must be non-negative and it must integrate to one over the whole line, $1=\int_{-\infty}^{\infty} f(t) d t$.
- Expected value of a function of a random variable with a continuous distribution: if the distribution of $X$ has density $f$ then

$$
\mathbb{E} H(X)=\int_{-\infty}^{\infty} H(x) f(x) d x
$$

- Be very careful not to confuse the formulae for expectations in the discrete and continuous cases. Think again if you find yourself integrating probabilities or summing expressions involving probability densities.

## Examples for Chapter 6

## Example 1.

Functions of a random variable with a continuous distribution.
Suppose $X$ has a uniform distribution on the interval $(-\pi / 2, \pi / 2)$. That is, it has a continuous distribution given by the density function

$$
f(x)= \begin{cases}1 / \pi & \text { for }-\pi / 2<x<\pi / 2 \\ 0 & \text { elsewhere }\end{cases}
$$

Let a new random variable be defined by $Y=\tan (X)$. It takes values over the whole real line. For a fixed real $y$, and a positive $\delta$, we have

$$
\begin{equation*}
y \leq Y \leq y+\delta \quad \text { if and only if } \quad x \leq X \leq x+\epsilon \tag{*}
\end{equation*}
$$

where $x$ and $\epsilon$ are related to $y$ and $\delta$ by the equalities

$$
y=\tan (x) \quad \text { and } \quad y+\delta=\tan (x+\epsilon)
$$

By Calculus, for small $\delta$,

$$
\delta=\epsilon \times \frac{\tan (x+\epsilon)-\tan (x)}{\epsilon} \approx \frac{\epsilon}{\cos ^{2} x} .
$$

Compare with the definition of the derivative:

$$
\lim _{\epsilon \rightarrow 0} \frac{\tan (x+\epsilon)-\tan (x)}{\epsilon}=\frac{d \tan (x)}{d x}=\frac{1}{\cos ^{2} x} .
$$

Thus

$$
\begin{aligned}
\mathbb{P}\{y \leq Y \leq y+\delta\} & =\mathbb{P}\{x \leq X \leq x+\epsilon\} \\
& \approx \epsilon f(x) \\
& \approx \frac{\delta \cos ^{2} x}{\pi}
\end{aligned}
$$

We need to express $\cos ^{2} x$ as a function of $y$. Note that

$$
1+y^{2}=1+\frac{\sin ^{2} x}{\cos ^{2} x}=\frac{\cos ^{2} x+\sin ^{2} x}{\cos ^{2} x}=\frac{1}{\cos ^{2} x}
$$

Thus $Y$ has a continuous distribution with density

$$
g(y)=\frac{1}{\pi\left(1+y^{2}\right)} \quad \text { for }-\infty<y<\infty .
$$

## Remark. The distribution defined by this density is called the Cauchy.

For functions that are not one-to-one, the analog of $(*)$ can require a little more work. In general, we can consider a random variable $Y$ defined as $H(X)$, a function of another random variable. If $X$ has a continous distribution with density $f$, and if $H$ is a smooth function with derivative $H^{\prime}$, then we can calculate a density for $Y$ by an extension of the method above.

A small interval $[y, y+\delta]$ in the range of values taken by $Y$ can correspond to a more complicated range of values for $X$. For instance, it might consist of a union of several intervals $\left[x_{1}, x_{1}+\epsilon_{1}\right],\left[x_{2}, x_{2}+\epsilon_{2}\right], \ldots$. The number of pieces in the $X$ range might be different for different values of $y$.

From the representation of $\{y \leq Y \leq y+\delta\}$ as a disjoint union of events

$$
\left\{x_{1} \leq X \leq x_{1}+\epsilon_{1}\right\} \cup\left\{x_{2} \leq X \leq x_{2}+\epsilon_{2}\right\} \cup \ldots,
$$

we get, via the defining property of the density $f$ for $X$,

$$
\begin{aligned}
\mathbb{P}\{y \leq Y \leq y+\} & =\mathbb{P}\left\{x_{1} \leq X \leq x_{1}+\epsilon_{1}\right\}+\mathbb{P}\left\{x_{2} \leq X \leq x_{2}+\epsilon_{2}\right\}+\ldots \\
& \approx \epsilon_{1} f\left(x_{1}\right)+\epsilon_{2} f\left(x_{2}\right)+\ldots
\end{aligned}
$$

For each small interval, the ratio of $\delta$ to $\epsilon_{i}$ is close to the derivative of the function $H$ at the corresponding $x_{i}$. That is, $\epsilon_{i} \approx \delta / H^{\prime}\left(x_{i}\right)$.

Adding the contributions from each such interval, we then have an approximation that tells us the density for $Y$,

$$
\mathbb{P}\{y \leq Y \leq y+\delta\} \approx \delta\left(\frac{f\left(x_{1}\right)}{H^{\prime}\left(x_{1}\right)}+\frac{f\left(x_{2}\right)}{H^{\prime}\left(x_{2}\right)}+\ldots\right)
$$

That is, the density for $Y$ at the particular point $y$ in its range equals

$$
\frac{f\left(x_{1}\right)}{H^{\prime}\left(x_{1}\right)}+\frac{f\left(x_{2}\right)}{H^{\prime}\left(x_{2}\right)}+\ldots
$$

Of course we should reexpress each $x_{i}$ as a function of $y$, to get the density in a more tractable form.

## Example 2.

Expectation of a random variable with a continuous distribution: if the distribution of $X$ has density $f$ then $\mathbb{E} H(X)=\int_{-\infty}^{+\infty} H(x) f(x) d x$.

Let $Y=H(X)$ be a new random variable, defined as a function of $X$. Calculate $\mathbb{E} Y$ by an approximation argument similar to the one used in Example $<1>$.

Cut the range of values that might be taken by $Y$ into disjoint intervals of the form $n \delta \leq y<(n+1) \delta$, for an arbitrarily small, positive $\delta$. Write $A_{n}$ for the corresponding set of $x$ values. That is, for each $x$ in $\mathbb{R}$,

$$
n \delta \leq H(x)<(n+1) \delta \quad \text { if and only if } \quad x \in A_{n} .
$$

We now have simple upper and lower bounds for $H$ :

$$
\begin{aligned}
H_{\delta}(x) \leq H(x) \leq & \delta+H_{\delta}(x) \quad \text { for every real } x \\
& \quad \text { where } H_{\delta}(x)=\sum_{n} n \delta \mathbb{\{}\left\{x \in A_{n}\right\} .
\end{aligned}
$$

(You should check the inequalities when $x \in A_{n}$, for each possible integer n.) Consequently

$$
\mathbb{E} H_{\delta}(X) \leq \mathbb{E} H(X) \leq \delta+\mathbb{E} H_{\delta}(X)
$$

and

$$
\int_{-\infty}^{+\infty} H_{\delta}(x) f(x) d x \leq \int_{-\infty}^{+\infty} H(x) f(x) d x \leq \delta+\int_{-\infty}^{+\infty} H_{\delta}(x) f(x) d x
$$

More concisely,

$$
\left|\mathbb{E} H_{\delta}(X)-\mathbb{E} H(X)\right| \leq \delta \quad \text { and } \quad\left|\int_{-\infty}^{+\infty} H_{\delta}(x) f(x) d x-\int_{-\infty}^{+\infty} H(x) f(x) d x\right| \leq \delta
$$

The random variable $H_{\delta}(X)$ has a discrete distribution whose expectation you know how to calculate:

$$
\begin{array}{rlc}
\mathbb{E} H_{\delta}(X) & =\mathbb{E} \sum_{n} n \delta \mathbb{I}\left\{X \in A_{n}\right\} \quad \text { expectation of a countable sum } \\
& =\sum_{n} n \delta \mathbb{P}\left\{X \in A_{n}\right\} \quad \text { because } \mathbb{E} \mathbb{I}\left\{X \in A_{n}\right\}=\mathbb{P}\left\{X \in A_{n}\right\} \\
& =\sum_{n} n \delta \int_{-\infty}^{+\infty} \mathbb{I}\left\{x \in A_{n}\right\} f(x) d x \quad \text { definition of } f \\
& =\int_{-\infty}^{+\infty} H_{\delta}(x) f(x) d x \quad \text { take sum inside integral. }
\end{array}
$$

From the inequalities ( $\star$ ) and the last equality deduce that

$$
\left|\mathbb{E} H(X)=\int_{-\infty}^{+\infty} H(x) f(x) d x\right| \leq 2 \delta
$$

for arbitrarily small $\delta>0$. The asserted representation for $\mathbb{E} H(X)$ follows.
Remark. Compare with the formula for a random variable $X^{*}$ taking only a discrete set of values $x_{1}, x_{2}, \ldots$,

$$
\mathbb{E} H\left(X^{*}\right)=\sum_{i} H\left(x_{i}\right) \mathbb{P}\left\{X^{*}=x_{i}\right\}
$$

In the passage from discrete to continuous distributions, discrete probabilities get replaced by densities and sums get replaced by integrals.

## Example 3.

Expected value and variance $N\left(\mu, \sigma^{2}\right)$.
If $X \sim N\left(\mu, \sigma^{2}\right)$ its density function is

$$
\begin{aligned}
f(x) & =\frac{1}{\sigma \sqrt{2 \pi}} \exp \left(\frac{-(x-\mu)^{2}}{2 \sigma^{2}}\right) \quad \text { for }-\infty<x<\infty \\
& =\frac{1}{\sigma} \phi\left(\frac{x-\mu}{\sigma}\right) \quad \text { where } \phi(y):=(2 \pi)^{-1 / 2} \exp \left(-y^{2} / 2\right)
\end{aligned}
$$

Calculate, using a change of variable $y=(x-\mu) / \sigma$.

$$
\begin{aligned}
\mathbb{E} X & =\int_{-\infty}^{+\infty} x f(x) d x \\
& =\int_{-\infty}^{+\infty}(\mu+\sigma y) \phi(y) d y \\
& =\mu \int_{-\infty}^{+\infty} \phi(y) d y+\sigma \int_{-\infty}^{+\infty} y \phi(y) d y \\
& =\mu .
\end{aligned}
$$

The second integral vanishes because $y \phi(y)=-(-y) \phi(-y)$.
Similarly

$$
\begin{aligned}
\operatorname{var}(X) & =\mathbb{E}(X-\mu)^{2} \\
& =\int_{-\infty}^{+\infty}(x-\mu)^{2} f(x) d x \\
& =\sigma^{2} \int_{-\infty}^{+\infty} y^{2} \phi(y) d y \\
& =\sigma^{2}
\end{aligned}
$$

using integration by parts and $\frac{d}{d y} \phi(y)=-y \phi(y)$.

## Example 4.

Suppose $X$ and $Y$ are independent random variables, each with a Uniform $[0,1]$ distribution. Show that $\mathbb{P}\{X=Y\}=0$.

The event $\{X=Y=1\}$ is a subset of $\{X=1\}$, which has zero probability. The other possibilities are almost as easy to dispose of: for each positive integer $n$,

$$
\{X=Y<1\} \subset \cup_{i=0}^{n-1}\{i / n \leq X<(i+1) / n \text { and } i / n \leq Y<(i+1) / n\}
$$

a disjoint union of events each with probability $1 / n^{2}$, by independence. Thus

$$
\mathbb{P}\{X=Y<1\} \leq n\left(1 / n^{2}\right)=1 / n \quad \text { for every } n
$$

It follows that $\mathbb{P}\{X=Y\}=0$.
A similar calculation shows that $\mathbb{P}\{X=Y\}=0$ for independent random variables with any pair of continuous distributions.

## Example 5.

The distribution of the order statistics from the uniform distribution.
Suppose $U_{1}, U_{2}, \ldots, U_{n}$ are independent random variables, each with distribution Uniform $[0,1]$. That is,

$$
\mathbb{P}\left\{a \leq U_{i} \leq b\right\}=\int_{a}^{b} h(x) d x \quad \text { for all real } a, b,
$$

where

$$
h(x)= \begin{cases}1 & \text { if } 0<x<1 \\ 0 & \text { otherwise } .\end{cases}
$$

The $U_{i}$ 's define $n$ points in the unit interval. If we measure the distance of each point from 0 we obtain random variables $0 \leq T_{1}<T_{2}<\cdots<T_{n} \leq 1$, the values $U_{1}, \ldots, U_{n}$ rearranged into increasing order. (Example $<4>$ lets me ignore ties.) For $n=6$, the picture (with $T_{5}$ and $T_{6}$ not shown) looks like:

If we repeated the process by generating a new sample of $U_{i}$ 's, we would probably not have $U_{4}$ as the smallest, $U_{1}$ as the second smallest, and so on. That is, $T_{1}$ might correspond to a different $U_{i}$.

The random variable $T_{k}$, the $k$ th smallest of the ordered values, is usually called the $k$ th order statistic. It takes a continuous range of values. It has a continuous distribution. What is its density function?

For a very short interval $[t, t+\delta]$, with $0<t<t+\delta<1$ and $\delta$ very small, we need to show that $\mathbb{P}\left\{t \leq T_{k} \leq t+\delta\right\}$ is roughly proportional to $\delta$, then determine $f(t)$, the constant of proportionality.

Write $N$ for the number of $U_{i}$ points that land in $[t, t+\delta]$. To get $t \leq T_{k} \leq t+\delta$ we must have $N \geq 1$. If $N=1$ then we must have exactly $k-1$ points in $[0, t)$ to get $t \leq T_{k} \leq t+\delta$. If $N \geq 2$ then it becomes more complicated to describe all the ways that we would get $t \leq T_{k} \leq t+\delta$. Luckily for us, the contributions from all those complicated expressions will turn out to be small enough to ignore if $\delta$ is small. Calculate.

$$
\begin{aligned}
\mathbb{P}\left\{t \leq T_{k} \leq t+\delta\right\}= & \mathbb{P}\{N=1 \text { and exactly } k-1 \text { points in }[0, t)\} \\
& +\mathbb{P}\left\{N \geq 2 \text { and } t \leq T_{k} \leq t+\delta\right\} .
\end{aligned}
$$

Let me first dispose of the second contribution, where $N \geq 2$. The event

$$
F_{2}=\{N \geq 2\} \cap\left\{t \leq T_{k} \leq t+\delta\right\}
$$

is a subset of the union

$$
\cup_{1<i<j \leq n}\left\{U_{i}, U_{j} \text { both in }[t, t+\delta]\right\}
$$

Put another way,

$$
\mathbb{I}_{F_{2}} \leq \sum_{1 \leq i<j \leq n} \mathbb{I}\left\{U_{i}, U_{j} \text { both in }[t, t+\delta]\right\} .
$$

Take expectations of both sides to deduce that

$$
\mathbb{P} F_{2} \leq \sum_{1 \leq i<j \leq n} \mathbb{P}\left\{U_{i}, U_{j} \text { both in }[t, t+\delta]\right\}
$$

By symmetry, all $\binom{n}{2}$ terms in the sum are equal to

$$
\begin{aligned}
& \mathbb{P}\left\{U_{1}, U_{2} \text { both in }[t, t+\delta]\right\} \\
& \quad=\mathbb{P}\left\{t \leq U_{1} \leq t+\delta\right\} \mathbb{P}\left\{t \leq U_{2} \leq t+\delta\right\} \quad \text { by independence } \\
& \quad=\delta^{2} .
\end{aligned}
$$

Thus $\mathbb{P} F_{2} \leq\binom{ n}{2} \delta^{2}$, which tends to zero much faster than $\delta$ as $\delta \rightarrow 0$. (The value of $n$ stays fixed throughout the calculation.)

Next consider the contribution from the event

$$
F_{1}=\{N=1\} \cap\{\text { exactly } k-1 \text { points in }[0, t)\} .
$$

Break $F_{1}$ into disjoint events like

$$
\left\{U_{1}, \ldots, U_{k-1} \text { in }[0, t), U_{k} \text { in }[t, t+\delta], U_{k+1}, \ldots, U_{n} \text { in }(t+\delta, 1]\right\} .
$$

Again by virtue of the independence between the $\left\{U_{i}\right\}$, this event has probability

$$
\mathbb{P}\left\{U_{1}<t\right\} \mathbb{P}\left\{U_{2}<t\right\} \ldots \mathbb{P}\left\{U_{k-1}<t\right\} \mathbb{P}\left\{U_{k} \text { in }[t, t+\delta]\right\} \mathbb{P}\left\{U_{k+1}>t+\delta\right\} \ldots \mathbb{P}\left\{U_{n}>t+\delta\right\},
$$

Invoke the defining property of the uniform distribution to factorize the probability as

$$
t^{k-1} \delta(1-t-\delta)^{n-k}=t^{k-1}(1-t)^{n-k} \delta+\text { terms of order } \delta^{2} \text { or smaller. }
$$

How many such pieces are there? There are $\binom{n}{k-1}$ ways to choose the $k-1$ of the $U_{i}$ 's to land in $[0, t)$, and for each of these ways there are $n-k+1$ ways to choose the single observation to land in $[t, t+\delta]$. The remaining observations must go in $(t+\delta, 1]$. We must add up

$$
\binom{n}{k-1} \times(n-k+1)=\frac{n!}{(k-1)!(n-k)!}
$$

contributions with the same probability to calculate $\mathbb{P} F_{1}$.
Consolidating all the small contributions from $\mathbb{P} F_{1}$ and $\mathbb{P} F_{2}$ we then get
$\mathbb{P}\left\{t \leq T_{k} \leq t+\delta\right\}=\frac{n!}{(k-1)!(n-k)!} t^{k-1}(1-t)^{n-k} \delta+$ terms of order $\delta^{2}$ or smaller.
That is, the distribution of $T_{k}$ is continuous with density function

$$
f(t)=\frac{n!}{(k-1)!(n-k)!} t^{k-1}(1-t)^{n-k} \quad \text { for } 0<t<1
$$

Outside $(0,1)$ the density is zero.
Remark. It makes no difference how we define $f(t)$ at $t=0$ and $t=1$, because it can have no effect on integrals $\int_{a}^{b} f(t) d t$.

From the fact that the density must integrate to 1 , we get

$$
1=\int_{-\infty}^{0} 0 d t+\frac{n!}{(k-1)!(n-k)!} \int_{0}^{1} t^{k-1}(1-t)^{n-k} d t+\int_{1}^{\infty} 0 d t
$$

That is,

$$
\int_{0}^{1} t^{k-1}(1-t)^{n-k} d t=\frac{(k-1)!(n-k)!}{n!}
$$

a fact that you might try to prove by direct calculation.

## Example 6.

Binomial tail probabilities from beta distributions.
In principle it is easy to calculate probabilities such as $\mathbb{P}\{\operatorname{Bin}(30, p) \geq 17\}$ for various values of $p$ : one has only to sum the series

$$
\binom{30}{17} p^{17}(1-p)^{13}+\binom{30}{18} p^{18}(1-p)^{12}+\cdots+(1-p)^{30}
$$

With a computer (using R, for example) such a task would not be as arduous as it used to be back in the days of hand calculation. We could also use a normal approximation. However, there is another method based on the facts about the order statistics, which gives an exact integral expression for the Binomial tail probability.

The relationship becomes clear from a special method for simulating coin tosses. For a fixed $n$ (such as $n=30$ ), generate independently $n$ random variables $U_{1}, \ldots, U_{n}$, each distributed uniformly on $[0,1]$. Fix a $p$ in $[0,1]$. Then the independent events

$$
\left\{U_{1} \leq p\right\},\left\{U_{2} \leq p\right\}, \ldots,\left\{U_{n} \leq p\right\}
$$

are like $n$ independent flips of a coin that lands heads with probability $p$. The number, $X_{n}$, of such events that occur has a $\operatorname{Bin}(n, p)$ distribution.

As in Example $<5>$, write $T_{k}$ for the $k$ th smallest value when the $U_{i}$ 's are sorted into increasing order.

The random variables $X_{n}$ and $T_{k}$ are related by an equivalence,

$$
X_{n} \geq k \text { if and only if } T_{k} \leq p
$$

That is, there are $k$ or more of the $U_{i}$ 's in $[0, p]$ if and only if the $k$ th smallest of all the $U_{i}$ 's is in $[0, p]$. Thus

$$
\mathbb{P}\left\{X_{n} \geq k\right\}=\mathbb{P}\left\{T_{k} \leq p\right\}=\frac{n!}{(k-1)!(n-k)!} \int_{0}^{p} t^{k-1}(1-t)^{n-k} d t .
$$

The density for the distribution of $T_{k}$ comes from Example $<5>$.

## Chapter 7

## Conditioning on a random variable with a continuous distribution

At this point in the course I hope you understand the importance of the conditioning formula

$$
\mathbb{E}(Y)=\sum_{i} \mathbb{P}\left(F_{i}\right) \mathbb{E}\left(Y \mid F_{i}\right)
$$

for finite or countably infinite collections of disjoint events $F_{i}$ for which $\sum_{i} \mathbb{P} F_{i}=1$. As a particular case, if $X$ is a random variable that takes only a discrete set of values $\left\{x_{1}, x_{2}, \ldots\right\}$ then

$$
\mathbb{E}(Y)=\sum_{i} \mathbb{P}\left\{X=x_{i}\right\} \mathbb{E}\left(Y \mid X=x_{i}\right)
$$

This formula can be made to look simpler by the introduction of the function

$$
h(x)=\mathbb{E}(Y \mid X=x) .
$$

For then
$(*) \quad \mathbb{E}(Y)=\sum_{i} \mathbb{P}\left\{X=x_{i}\right\} h\left(x_{i}\right)=\mathbb{E}(h(X))$.
Throughout the course I have been working with examples where you could figure out things like $\mathbb{E}(Y \mid X=x)$ or $\mathbb{P}(A \mid F)$ by identifying the probabilistic mechanism corresponding to the probability $\mathbb{P}(\cdot \mid X=x\}$ or $\mathbb{P}(\cdot \mid F)$. In a few cases, you could also have calculated directly from
$(* *) \quad \mathbb{P}(A \mid F)=\frac{\mathbb{P}(A F)}{\mathbb{P} F}=\frac{\mathbb{P}(F \mid A) \mathbb{P} A}{\mathbb{P} F}$
Of course this formula only makes sense if $\mathbb{P} F \neq 0$.
If the random variable $X$ has a continuous distribution, you still have the possibility of calculating things like $\mathbb{E}(Y \mid X=x)$ and $\mathbb{P}(A \mid X=x)$ by recognizing an appropriate probabilistic mechanism corresponding to $\mathbb{P}(\cdot \mid X=x)$. But you won't have much luck in putting $F=\{X=x\}$ in $(* *)$ because $\mathbb{P}\{X=x\}=0$ for a continuous distribution. Nevertheless, as I will soon explain, there is a formula similar to (*) that works when $X$ has a continuous distribution with density function $f$. As before write $h(x)$ for $\mathbb{E}(Y \mid X=x)$. I will explain why

$$
\begin{equation*}
\mathbb{E}(Y)=\mathbb{E}(h(X))=\int_{-\infty}^{\infty} h(x) f(x) d x . \tag{y}
\end{equation*}
$$

Remark. As a special case, when $Y$ equals the indicator function of an event $B$, the formula reduces to

$$
\mathbb{P} B=\int_{-\infty}^{\infty} \mathbb{P}(B \mid X=x) f(x) d x .
$$

There are several ways to arrive at formula ( $\mathbf{\Psi}$ ). The most direct relies on the plausible assertion that

$$
\mathbb{E}(Y \mid X \in J) \approx h(x) \quad \text { if } J \text { is a small interval with } x \in J
$$

When $\mathbb{P}\{X \in J\}>0$ we are effectively back in the discrete setting $(* *)$.
Condition to get a formula analogous to (*). For each $\epsilon>0$ the intervals $J_{i}=[i \epsilon, i \epsilon+\epsilon)$ provide a partition of the real line into countably many disjoint sets as $i$ ranges over all integers (both positive and negative). If $\epsilon$ is very small,

$$
\mathbb{E} Y=\sum_{i} \mathbb{P}\left\{X \in J_{i}\right\} \mathbb{E}\left(Y \mid X \in J_{i}\right\} \approx \sum_{i} \epsilon f(i \epsilon) h(i \epsilon) \approx \int_{-\infty}^{\infty} h(x) f(x) d x
$$

We can hope that the combined errors of all the approximation will disappear in the limit as $\epsilon$ tends to zero.

Alternatively, I could start from a slightly less intuitive assumption that $\mathbb{E} Y$ should be nonnegative if $\mathbb{E}(Y \mid X=x) \geq 0$ for every $x$. First replace $Y$ by $Y-h(X)$ to get

$$
\mathbb{E}(Y-h(X) \mid X=x)=\mathbb{E}(Y \mid X=x)-h(x)=0,
$$

which, by the assumed nonnegativity property, gives $\mathbb{E}(Y-h(X)) \geq 0$. A similar argument applied to $h(X)-Y$ gives $\mathbb{E}(h(X)-Y) \geq 0$. Equality ( $\mathbf{(})$ follows.

Remark. Notice that formula ( $\mathbf{(}$ ) also implies that

$$
\begin{aligned}
& \text { ( } \mathbb{E}(Y g(X))=\mathbb{E}(g(X) h(X)) \quad \text { at least for bounded functions } g \\
& \text { because } \mathbb{E}(Y g(X) \mid X=x)=g(x) h(x) \text {. In advanced probability theory, the } \\
& \text { treatment of conditional expectations starts by taking ( } \mathbb{Z}) \text { as a desirable } \\
& \text { property. One then shows that there exists a random variable of the form } h(X) \text {, } \\
& \text { which is uniquely determined up to trivial changes on sets of zero probability, } \\
& \text { for which the desired property holds. Essentially } h(X) \text { becomes the best } \\
& \text { approximation to } Y \text {, in some sense, using only information given by } X \text {. } \\
& \text { If (shudder!) I had started with this abstract approach, I would have needed } \\
& \text { to show that conditional expectations have the properties that I have taken as } \\
& \text { axiomatic for Stat } 241 / 541 \text {. }
\end{aligned}
$$

Formula ( $\mathbf{( 1 s )}$ ) crucial in finding the distribution for a sum of two independent random variables, each with a continuous distribution.
$<1>$

Example. If $X$ and $Y$ are independent, each with the Uniform $(0,1)$ distribution, find the distribution of $X+Y$.

The convolution formula also establishes a vital fact about sums of independent normals.
$<3>\quad$ Example. If $X_{1}$ and $X_{2}$ are independent random variables with $X_{1} \sim N\left(\mu_{1}, \sigma_{1}^{2}\right)$ and $X_{2} \sim N\left(\mu_{2}, \sigma_{2}^{2}\right)$, then $X_{1}+X_{2} \sim N\left(\mu_{1}+\mu_{2}, \sigma_{1}^{2}+\sigma_{2}^{2}\right)$.

This fact lurks behind the central limit, a general approximation theorem for sums of independent random variables, which will be discussed in the next Chapter.

## Examples for Chapter 7

## Example 1

Suppose $X$ has a continuous distribution with density $f$ and $Y$ has a continuous distribution with density $g$. If $X$ and $Y$ are independent show that the random variable $Z=X+Y$ has a continuous distribution with density

$$
h(z)=\int_{-\infty}^{\infty} g(z-x) f(x) d x \quad \text { for all real } z .
$$

As usual, consider a small, positive $\delta$. Then

$$
\begin{aligned}
\mathbb{P}\{ & z \leq Z \leq z+\delta\} \\
& =\int_{-\infty}^{+\infty} \mathbb{P}\{z \leq X+Y \leq z+\delta \mid X=x\} f(x) d x \quad \text { by }(\mathbf{X}) \\
& =\int_{-\infty}^{+\infty} \mathbb{P}\{z \leq x+Y \leq z+\delta \mid X=x\} f(x) d x \quad \text { conditioning on } X=x \\
& =\int_{-\infty}^{+\infty} \mathbb{P}\{z-x \leq Y \leq z-x+\delta \mid X=x\} f(x) d x \\
& =\int_{-\infty}^{+\infty} \mathbb{P}\{z-x \leq Y \leq z-x\} f(x) d x \quad \text { independence } \\
& \approx \int_{-\infty}^{+\infty} \delta g(z-x) f(x) d x \quad \text { density for } Y
\end{aligned}
$$

That is,

$$
\mathbb{P}\{z \leq Z \leq z+\delta\} \approx \delta h(x)
$$

as asserted.

## Example 2

If $X$ and $Y$ are independent, each with the Uniform $(0,1)$ distribution, find the distribution of $X+Y$.

The $\operatorname{Uniform}(0,1)$ has density function $f(x)=\mathbb{I}\{0<x<1\}$, that is,

$$
f(x)= \begin{cases}1 & \text { if } x \in(0,1) \\ 0 & \text { otherwise }\end{cases}
$$

The density function $h$ for the distribution of $X+Y$ is given by

$$
\begin{aligned}
h(z) & =\int_{-\infty}^{\infty} \mathbb{I}\{0<z-x<1\} \mathbb{I}\{0<x<1\} d x \\
& =\int_{-\infty}^{\infty} \mathbb{I}\{x<z, x>z-1,0<x<1\} d x \\
& =\int_{-\infty}^{\infty} \mathbb{I}\{\max (0, z-1)<x<\min (1, z)\} d x .
\end{aligned}
$$

If $z \leq 0$ or $z \geq 2$ there are no values of $x$ that satisfy the pair of inequalities in the final indicator function; for those cases the indicator function is zero. If $0<z \leq 1$ the indicator becomes $\mathbb{I}\{0<x<z\}$, so that the corresponding integral equals

$$
\int_{-\infty}^{\infty} \mathbb{I}\{0<x<z\} d x=\int_{0}^{z} 1 d x=z
$$

Similarly, if $1<z<2$ the integral becomes

$$
\int_{-\infty}^{\infty} \mathbb{I}\{z-1<x<1\} d x=\int_{z-1}^{1} 1 d x=2-z
$$

In summary,

$$
h(z)=\left\{\begin{array}{ll}
0 & \text { if } z \leq 0 \text { or } z \geq 2 \\
z & \text { if } 1<z \leq 1 \\
2-z & \text { if } 1<z<2
\end{array} .\right.
$$

More succinctly, $h(z)=\max (0, \min (z, 2-z))$.

## Example 3

If $X_{1}$ and $X_{2}$ are independent random variables with $X_{1} \sim N\left(\mu_{1}, \sigma_{1}^{2}\right)$ and $X_{2} \sim N\left(\mu_{2}, \sigma_{2}^{2}\right)$, then $X_{1}+X_{2} \sim N\left(\mu_{1}+\mu_{2}, \sigma_{1}^{2}+\sigma_{2}^{2}\right)$.

Let me simplify the algebra by writing $X_{i}=\mu_{i}+\sigma_{i} Z_{i}$, where $Z_{1}$ and $Z_{2}$ are independent standard normals. Then we have $X_{1}+X_{2}=\mu_{1}+\mu_{2}+\sigma_{1} Z_{1}+\sigma_{2} Z_{2}$. It will suffice we show that $W=\sigma_{1} Z_{1}+\sigma_{2} Z_{2}$ has a $N\left(0, \sigma_{1}^{2}+\sigma_{2}^{2}\right)$ distribution.

The convolution formula gives the density for the distribution of $W$,

$$
h(z)=\frac{1}{\sigma_{1} \sigma_{2} 2 \pi} \int_{-\infty}^{\infty} \exp \left(-\frac{(z-x)^{2}}{2 \sigma_{1}^{2}}-\frac{x^{2}}{2 \sigma_{2}^{2}}\right) d x .
$$

The exponent expands to

$$
-\frac{1}{2} x^{2}\left(\sigma_{1}^{-2}+\sigma_{2}^{-2}\right)+z x / \sigma_{1}^{2}-\frac{1}{2} z^{2} / \sigma_{1}^{2} .
$$

Make the change of variable $y=x / c$, with

$$
c=1 / \sqrt{\sigma_{1}^{-2}+\sigma_{2}^{-2}}=\sigma_{1} \sigma_{2} / \tau \quad \text { where } \tau=\sqrt{\sigma_{1}^{2}+\sigma_{2}^{2}} .
$$

The exponent becomes

$$
\begin{aligned}
& -\frac{1}{2}\left(y^{2}-2 z c y / \sigma_{1}^{2}+c^{2} z^{2} / \sigma_{1}^{4}\right)+\frac{1}{2} c^{2} z^{2} / \sigma_{1}^{4}-\frac{1}{2} z^{2} / \sigma_{1}^{2} \\
& =-\frac{1}{2}\left(y-z c / \sigma_{1}^{2}\right)^{2}-\frac{1}{2} z^{2} / \tau^{2} .
\end{aligned}
$$

The expression for $h(z)$ simplifies to

$$
\frac{1}{\tau 2 \pi} \exp \left(-\frac{z^{2}}{2 \tau^{2}}\right) \int_{-\infty}^{\infty} \exp \left(-\frac{1}{2}\left(y-z c / \sigma_{1}^{2}\right)^{2}\right) d y
$$

The change of variable $w=y-z c / \sigma_{1}^{2}$ then leaves an integral that equals $\sqrt{2 \pi}$.
All the sneaky changes of variable might leave you feeling that the argument is difficult. In fact I didn't have to be so careful. In the original convolution integral I had an exponent of the form $-C_{1} x^{2}+C_{2} x z-C_{3} z^{2}$ for some constants $C_{1}, C_{2}, C_{3}$. I completed the square to rewrite the exponent as $-C_{4}\left(y-C_{5} z\right)^{2}-C_{6} z^{2}$, where $y$ a linear function of $x$ and $C_{4}, C_{5}, C_{6}$ were new constants. A change of variable allowed me to integrate out the $y$, leaving an expression of the form $C_{7} \exp \left(-C_{6} z^{2}\right)$, which is clearly a $N\left(0, \tau^{2}\right)$ density for some $\tau$. I could have calculated $\tau$ directly by $\tau^{2}=\operatorname{var}(W)=\sigma_{1}^{2} \operatorname{var}\left(Z_{1}\right)+\sigma_{2}^{2} \operatorname{var}\left(Z_{2}\right)$.

## Chapter 8

## Central limit theorems

Recall that a random variable is said to have a normal distribution with expected value $\mu$ and standard deviation $\sigma$ if it has a continuous distribution with density

$$
f_{\mu, \sigma}(x)=\frac{1}{\sigma \sqrt{2 \pi}} \exp \left(-\frac{(x-\mu)^{2}}{2 \sigma^{2}}\right) \quad \text { for }-\infty<x<\infty .
$$

The normal distribution is denoted by $N\left(\mu, \sigma^{2}\right)$. The special case where $\mu=0$ and $\sigma=1$ is called the standard normal. The density function for this $N(0,1)$ distribution is usually denoted by $\phi(x):=(2 \pi)^{-1 / 2} e^{-x^{2} / 2}$.

Remember that $X$ has a $N\left(\mu, \sigma^{2}\right)$ distribution if and only if $(X-\mu) / \sigma$ has a standard normal distribution. That is, we can write $X=\mu+\sigma Z$ where $Z$ has a standard normal distribution.

The normal approximation to the binomial is just one example of a general phenomenon corresponding to the mathematical result known as the central limit theorem. Roughly stated, the theorem asserts:

If $X$ can be written as a sum of a large number of relatively small, independent random variables, then it has approximately a $N\left(\mu, \sigma^{2}\right)$ distribution, where $\mu=\mathbb{E} X$ and $\sigma^{2}=\operatorname{var}(X)$. Equivalently, the standardized variable $(X-\mu) / \sigma$ has approximately a standard normal distribution.

See the Appendix for an outline of a proof of a central limit theorem, if you are interested. You can safely ignore the Appendix.

Part of the reason for the ubiquity of the normal as an an approximation is an important stability property that was established in Chapter 7: If $X_{1}$ and $X_{2}$ are independent random variables with $X_{1} \sim N\left(\mu_{1}, \sigma_{1}^{2}\right)$ and $X_{2} \sim N\left(\mu_{2}, \sigma_{2}^{2}\right)$, then $X_{1}+X_{2} \sim N\left(\mu_{1}+\mu_{2}, \sigma_{1}^{2}+\sigma_{2}^{2}\right)$.

The normal distribution has many agreeable properties that make it easy to work with. Many statistical procedures have been developed under normality assumptions, with occasional offhand references to the central limit theorem to mollify anyone who doubts that all distributions are normal. That said, let me note that modern theory has been much concerned with possible harmful effects of unwarranted assumptions such as normality. The modern fix often substitutes huge amounts of computing for neat, closed-form, analytic expressions; but normality still lurks behind some of the modern data analytic tools.
$<1>\quad$ Example. A hidden normal approximation-the boxplot
The normal approximation is heavily used to give an estimate of variability for the results from sampling.
$<2>\quad$ Example. Normal approximations for sample means

## Examples for Chapter 8

## Example 1

The boxplot provides a convenient way of summarizing data (such as grades in Statistics $241 / 541$ ). The method is:
(i) arrange the data in increasing order
(ii) find the split points

$$
\begin{aligned}
\mathrm{LQ} & =\text { lower quartile: } 25 \% \text { of the data smaller than } \mathrm{LQ} \\
\mathrm{M} & =\text { median: } 50 \% \text { of the data smaller than } \mathrm{M} \\
\mathrm{UQ} & =\text { upper quartile: } 75 \% \text { of the data smaller than UQ }
\end{aligned}
$$

(iii) calculate IQR (= inter-quartile range) $=\mathrm{UQ}-\mathrm{LQ}$
(iv) draw a box with ends at LQ and UQ, and a dot or a line at M
(v) draw whiskers out to $\mathrm{UQ}+(1.5 \times \mathrm{IQR})$ and $\mathrm{LQ}-(1.5 \times \mathrm{IQR})$, but then trim them back to the most extreme data point in those ranges
(vi) draw dots for each individual data point outside the box and whiskers (There are various ways to deal with cases where the number of observations is not a multiple of four, or where there are ties, or ...)

Where does the $1.5 \times I Q R$ come from? Consider $n$ independent observations from a $N\left(\mu, \sigma^{2}\right)$ distribution. The proportion of observations smaller than any fixed $x$ should be approximately equal to $\mathbb{P}\{W \leq x\}$, where $W$ has a $N\left(\mu, \sigma^{2}\right)$ distribution. From normal tables (or a computer),

$$
\mathbb{P}\{W \leq \mu+.675 \sigma\} \approx .75 \quad \text { and } \quad \mathbb{P}\{W \leq \mu-.675 \sigma\} \approx .25
$$

and, of course, $\mathbb{P}\{W \leq \mu\}=.5$. For the sample we should expect

$$
\mathrm{LQ} \approx \mu-.675 \sigma \quad \text { and } \quad \mathrm{UQ} \approx \mu+.675 \sigma \quad \text { and } \quad \mathrm{M} \approx \mu
$$

and consequently, $\mathrm{IQR} \approx 1.35 \sigma$. Check that $0.675+(1.5 \times 1.35)=2.70$. Before trimming, the whiskers should approximately reach to the ends of the range $\mu \pm$ $2.70 \sigma$. From computer (or tables),

$$
\mathbb{P}\{W \leq \mu-2.70 \sigma\}=\mathbb{P}\{W \geq \mu+2.70 \sigma\}=.003
$$

Only about $0.6 \%$ of the sample should be out beyond the whiskers.

## Example 2

Chapter 4 gave the expected value and variance of a sample mean $\bar{Y}$ for a sample of size $n$ from a population $\left\{y_{1}, y_{2}, \ldots, y_{N}\right\}$ :

$$
\mathbb{E} \bar{Y}=\bar{y}=\frac{1}{N} \sum_{i=1}^{N} y_{i}
$$

and, for sampling with replacement,

$$
\operatorname{var}(\bar{Y})=\sigma^{2} / n \quad \text { where } \sigma^{2}=\sum_{i=1}^{N}\left(y_{i}-\bar{y}\right)^{2} / N .
$$

If $Z$ has a $N(0,1)$ distribution,

$$
\mathbb{P}\{-1.96 \leq Z \leq 1.96\} \approx 0.95 .
$$

The standardized random variable $(\bar{Y}-\bar{y}) / \sqrt{\sigma^{2} / n}$ is well approximated by the $N(0,1)$. Thus

$$
\mathbb{P}\left\{-\frac{1.96 \sigma}{\sqrt{n}} \leq \bar{Y}-\bar{y} \leq \frac{1.96 \sigma}{\sqrt{n}}\right\} \approx 0.95 .
$$

Before we sample, we can assert that we have about a $95 \%$ chance of getting a value of $\bar{Y}$ in the range $\bar{y} \pm 1.96 \sigma / \sqrt{n}$. (For the post-sampling interpretation of the approximation, you should take Statistics $242 / 542$.)

Of course, we would not know the value $\sigma$, so it must be estimated.
For sampling without replacement, the variance of the sample mean is multiplied by the correction factor $(N-n) /(N-1)$. The sample mean is no longer an average of many independent summands, but the normal approximation can still be used. (The explanation would take me too far beyond 241/541.)

## Appendix: Lindeberg's method for the Central Limit Theorem

We have $X=X_{1}+X_{2}+\cdots+X_{n}$, a sum of a lot of small, independent contributions. If all the $X_{i}$ 's are normally distributed, repeated appeals to Example <?? $>$ show that $X$ is also normally distributed.

If the $X_{i}$ 's are not normal, we replace them one at a time by new independent random variables $Y_{i}$ for which $\mathbb{E} Y_{i}=\mathbb{E} X_{i}$ and $\operatorname{var}\left(Y_{i}\right)=\operatorname{var}\left(X_{i}\right)$. It is easy to use Taylor's theorem to track the effect of the replacement if we consider smoooth functions of the sum.

For example, suppose $h$ has a lot of bounded, continuous derivatives. Write $S$ for $X_{1}+\cdots+X_{n-1}$. Then

$$
\begin{aligned}
\mathbb{E} h(X) & =\mathbb{E} h\left(S+X_{n}\right) \\
& =\mathbb{E}\left[h(S)+X_{n} h^{\prime}(S)+\frac{1}{2} X_{n}^{2} h^{\prime \prime}(S)+\frac{1}{6} X_{n}^{3} h^{\prime \prime \prime}(S)+\ldots\right] \\
& =\mathbb{E} h(S)+\mathbb{E} X_{n} \mathbb{E} h^{\prime}(S)+\frac{1}{2} \mathbb{E}\left(X_{n}^{2}\right) \mathbb{E} h^{\prime \prime}(S)+\frac{1}{6} \mathbb{E}\left(X_{n}^{3}\right) \mathbb{E}\left(h^{\prime \prime \prime}(S)\right)+\ldots
\end{aligned}
$$

In the last line, I have used the independence to factorize a bunch of products.
Exactly the same idea works for $h\left(S+Y_{n}\right)$. That is,

$$
\mathbb{E} h\left(S+Y_{n}\right)=\mathbb{E} h(S)+\mathbb{E} Y_{n} \mathbb{E} h^{\prime}(S)+\frac{1}{2} \mathbb{E}\left(Y_{n}^{2}\right) \mathbb{E} h^{\prime \prime}(S)+\frac{1}{6} \mathbb{E}\left(Y_{n}^{3}\right) \mathbb{E}\left(h^{\prime \prime \prime}(S)\right)+\ldots
$$

Subtract the two expansions, noting the cancellations caused by the matching of first and second moments for $X_{n}$ and $Y_{n}$.

$$
\mathbb{E} h\left(S+X_{n}\right)-\mathbb{E} h\left(S+Y_{n}\right)=\frac{1}{6} \mathbb{E}\left(X_{n}^{3}\right) \mathbb{E}\left(h^{\prime \prime \prime}(S)\right)+\cdots-\frac{1}{6} \mathbb{E}\left(Y_{n}^{3}\right) \mathbb{E}\left(h^{\prime \prime \prime}(S)\right)+\ldots
$$

A similar argument works if we replace the $X_{n-1}$ in $\mathbb{E} h\left(S+Y_{n}\right)$ by its companion $Y_{n-1}$. And so on. After we swap out all the $X_{i}$ 's we are left with
$E h(X)-\mathbb{E} h\left(Y_{1}+Y_{2}+\ldots Y_{n}\right)=$ a sum of quantities of third, or higher order.
A formal theorem would give a precise meaning to how small the $X_{i}$ 's have to be in order to make the "sum of quantities of third, or higher order" small enough to ignore.

If you were interested in expectations $\mathbb{E} h(X)$ for functions that are not smooth, as happens with $\mathbb{P}\{X \leq x\}$, you would need to approximate the non-smooth $h$ by a smooth function for which Lindeberg's method can be applied.

## Chapter 9

## Poisson approximations

The $\operatorname{Bin}(n, p)$ can be thought of as the distribution of a sum of independent indicator random variables $X_{1}+\cdots+X_{n}$, with $\left\{X_{i}=1\right\}$ denoting a head on the $i$ th toss of a coin. The normal approximation to the Binomial works best when the variance $n p(1-p)$ is large, for then each of the standardized summands $\left(X_{i}-p\right) / \sqrt{n p(1-p)}$ makes a relatively small contribution to the standardized sum.

When $n$ is large but $p$ is small, in such a way that $\lambda:=n p$ is not too large, a different type of approximation to the Binomial is better. The traditional explanation uses an approximation to $\mathbb{P}\{X=k\}$ for a fixed $k$. Consider two contributions separately. If $k$ is small compared with $n$,

$$
\begin{aligned}
\binom{n}{k} p^{k} & =\frac{n(n-1) \ldots(n-k+1)}{k!}\left(\frac{\lambda}{n}\right)^{k} \\
& =1 \times\left(1-\frac{1}{n}\right) \times \ldots\left(1-\frac{k-1}{n}\right) \frac{\lambda^{k}}{k!} \\
& \approx \frac{\lambda^{k}}{k!}
\end{aligned}
$$

and

$$
\log (1-p)^{n-k}=(n-k) \log \left(1-\frac{\lambda}{n}\right) \approx n\left(-\frac{\lambda}{n}\right)
$$

That is, $(1-p)^{n-k} \approx e^{-\lambda}$. Together the two approximations give

$$
\binom{n}{k} p^{k}(1-p)^{n-k} \approx \frac{\lambda^{k}}{k!} e^{-\lambda} .
$$

We have an approximation.

Definition. A random variable $Y$ is said to have a Poisson distribution with parameter $\lambda$ if it can take values in $\mathbb{N}_{0}$, the set of nonnegative integers, with probabilities

$$
\mathbb{P}\{Y=k\}=\frac{e^{-\lambda} \lambda^{k}}{k!} \quad \text { for } k=0,1,2, \ldots
$$

The parameter $\lambda$ must be positive. The distribution is denoted by Poisson $(\lambda)$.

That is, for $\lambda=n p$ not too large, the $\operatorname{Bin}(n, p)$ is (well?) approximated by the Poisson ( $\lambda$ ).

Modern probability methods have improved this rough approximation of the Binomial by the Poisson by giving useful bounds for the error of approximation. Moreover, the method of approximation also works in situations where the rare events do not all have the same probability of occurrence. For example, suppose $S=X_{1}+X_{2}+\cdots+X_{n}$, a sum of independent random variables where $X_{i}$ has a $\operatorname{Bin}\left(1, p_{i}\right)$ distribution, for constants $p_{1}, p_{2}, \ldots, p_{n}$ that are not necessarily all the same. If the $p_{i}$ 's are not all the same then $S$ does not have a Binomial distribution. Nevertheless, the Chen-Stein method can be used to show that

$$
\begin{aligned}
\frac{1}{2} \sum_{k \geq 0} & \left|\mathbb{P}\{S=k\}-e^{-\lambda} \frac{\lambda^{k}}{k!}\right| \\
& \leq \frac{1-e^{-\lambda}}{\lambda} \sum_{i=1}^{n} p_{i}^{2} \quad \text { where } \lambda=p_{1}+\cdots+p_{n} \\
& \leq \min \left(1, \frac{1}{\lambda}\right) \sum_{i=1}^{n} p_{i}^{2} \quad \text { by Mean Value theorem } \\
& \leq \min (1, \lambda) \max _{i} p_{i} .
\end{aligned}
$$

The method of proof is elementary - in the sense that it makes use of probabilistic techniques at the level of Statistics 241-but extremely subtle. See Barbour et al. (1992) for an extensive discussion of the method.

When all the $p_{i}$ are equal to some small $p$, Chen-Stein shows the error in approximating the $\operatorname{Binomial}(n, p)$ by the Poisson $(n p)$ is smaller than $\min \left(p, n p^{2}\right)$. This bound makes precise the traditional advice that the Poisson approximation is good "when $p$ is small and $n p$ is not too big". (In fact, the tradition was a bit conservative.)

Remark. Counts of rare events - such as the number of atoms undergoing radioactive decay during a short period of time, or the number of aphids on a leaf - are often modeled by Poisson distributions, at least as a first approximation.

The Poisson inherits several properties from the Binomial. For example, the $\operatorname{Bin}(n, p)$ has expected value $n p$ and variance $n p(1-p)$. One might suspect that the $\operatorname{Poisson}(\lambda)$ should therefore have expected value $\lambda=n(\lambda / n)$ and variance $\lambda=$ $\lim _{n \rightarrow \infty} n(\lambda / n)(1-\lambda / n)$. Also, the coin-tossing origins of the Binomial show that if $X$ has a $\operatorname{Bin}(m, p)$ distribution and $Y$ has a $\operatorname{Bin}(n, p)$ distribution independent of $X$, then $X+Y$ has a $\operatorname{Bin}(n+m, p)$ distribution. Putting $\lambda=m p$ and $\mu=n p$ one might then suspect that the sum of independent Poisson $(\lambda)$ and Poisson $(\mu)$ distributed random variables is Poisson $(\lambda+\mu)$ distributed. These suspicions are correct.

The Poisson approximation also applies in many settings where the trials are "almost independent", but not quite. Again the Chen-Stein method delivers impressively good bounds on the errors of approximation. For example, the method works well in two cases where the dependence takes an a simple form.

Once again suppose $S=X_{1}+X_{2}+\cdots+X_{n}$, where $X_{i}$ has a $\operatorname{Bin}\left(1, p_{i}\right)$ distribution, for constants $p_{1}, p_{2}, \ldots, p_{n}$ that are not necessarily all the same. Define $S_{-i}=S-X_{i}=\sum_{1 \leq j \leq n} \mathbb{I}\{j \neq i\} X_{j}$. I will call the random variables $X_{1}, \ldots, X_{n}$ positively associated if

$$
\mathbb{P}\left\{S_{-i} \geq k \mid X_{i}=1\right\} \geq \mathbb{P}\left\{S_{-i} \geq k \mid X_{i}=0\right\} \quad \text { for each } i \text { and each } k=0,1,2, \ldots
$$

and negatively associated if

$$
\mathbb{P}\left\{S_{-i} \geq k \mid X_{i}=1\right\} \leq \mathbb{P}\left\{S_{-i} \geq k \mid X_{i}=0\right\} \quad \text { for each } i \text { and each } k=0,1,2, \ldots
$$

With some work it can be shown that

$$
\begin{aligned}
& \frac{1}{2} \sum_{k \geq 0}\left|\mathbb{P}\{S=k\}-e^{-\lambda} \frac{\lambda^{k}}{k!}\right| \\
& \quad \leq\left(1-e^{-\lambda}\right) / \lambda \begin{cases}2 \sum_{i=1}^{n} p_{i}^{2}+2(\operatorname{var}(S)-\lambda) & \text { under positive association } \\
\lambda-\operatorname{var}(S) & \text { under negative association. }\end{cases}
\end{aligned}
$$

These bounds take advantage of the fact that $\operatorname{var}(S)$ would be exactly equal to $\lambda$ if $S$ had a Poisson $(\lambda)$ distribution.

The next Example illustrates both the classical approach and the Chen-Stein approach (via positive association) to deriving a Poisson approximation for a matching problem.

Example. Poisson approximation for a matching problem: assignment of $n$ letters at random to $n$ envelopes, one per envelope.

The Appendix to this Chapter provides a more detailed introduction to the Chen-Stein method, as applied to another aspect of the matching problem. (I have taken advantage of a few special features of the matching problem to simplify the exposition.) You could safely skip this Appendix. For more details, see the monograph by Barbour et al. (1992).

## Examples for Chapter 9

## Example 1

If $X$ has a Poisson $(\lambda)$ distribution, then $\mathbb{E} X=\operatorname{var}(X)=\lambda$. If also $Y$ has a Poisson $(\mu)$ distribution, and $Y$ is independent of $X$, then $X+Y$ has a Poisson $(\lambda+\mu)$ distribution.

Assertion (i) comes from a routine application of the formula for the expectation of a random variable with a discrete distribution.

$$
\begin{aligned}
\mathbb{E} X=\sum_{k=0}^{\infty} k \mathbb{P}\{X=k\} & =\sum_{k=1}^{\infty} k \frac{e^{-\lambda} \lambda^{k}}{k!} \quad \text { What happens to } k=0 ? \\
& =e^{-\lambda} \lambda \sum_{k-1=0}^{\infty} \frac{\lambda^{k-1}}{(k-1)!} \\
& =e^{-\lambda} \lambda e^{\lambda} \\
& =\lambda .
\end{aligned}
$$

Notice how the $k$ cancelled out one factor from the $k$ ! in the denominator.
If I were to calculate $\mathbb{E}\left(X^{2}\right)$ in the same way, one factor in the $k^{2}$ would cancel the leading $k$ from the $k$ !, but would leave an unpleasant $k /(k-1)$ ! in the sum. Too bad the $k^{2}$ cannot be replaced by $k(k-1)$. Well, why not?

$$
\begin{aligned}
\mathbb{E}\left(X^{2}-X\right) & =\sum_{k=0}^{\infty} k(k-1) \mathbb{P}\{X=k\} \\
& =e^{-\lambda} \sum_{k=2}^{\infty} k(k-1) \frac{\lambda^{k}}{k!} \quad \text { What happens to } k=0 \text { and } k=1 ? \\
& =e^{-\lambda} \lambda^{2} \sum_{k-2=0}^{\infty} \frac{\lambda^{k-2}}{(k-2)!} \\
& =\lambda^{2} .
\end{aligned}
$$

Now calculate the variance.

$$
\operatorname{var}(X)=\mathbb{E}\left(X^{2}\right)-(\mathbb{E} X)^{2}=\mathbb{E}\left(X^{2}-X\right)+\mathbb{E} X-(\mathbb{E} X)^{2}=\lambda
$$

For assertion (iii), first note that $X+Y$ can take only values $0,1,2 \ldots$ For a fixed $k$ in this range, decompose the event $\{X+Y=k\}$ into disjoint pieces whose probabilities can be simplified by means of the independence between $X$ and $Y$.

$$
\begin{aligned}
& \mathbb{P}\{X+Y=k\}= \\
& \mathbb{P}\{X=0, Y=k\}+\mathbb{P}\{X=1, Y=k-1\}+\cdots+\mathbb{P}\{X=k, Y=0\} \\
& =\mathbb{P}\{X=0\} \mathbb{P}\{Y=k\}+\mathbb{P}\{X=1\} \mathbb{P}\{Y=k-1\}+\cdots+\mathbb{P}\{X=k\} \mathbb{P}\{Y=0\} \\
& =\frac{e^{-\lambda} \lambda^{0}}{0!} \frac{e^{-\mu} \mu^{k}}{k!}+\cdots+\frac{e^{-\lambda} \lambda^{k}}{k!} \frac{e^{-\mu} \mu^{0}}{0!} \\
& =\frac{e^{-\lambda-\mu}}{k!}\left(\frac{k!}{0!k!} \lambda^{0} \mu^{k}+\frac{k!}{1!(k-1)!} \lambda^{1} \mu^{k-1}+\cdots+\frac{k!}{k!0!} \lambda^{k} \mu^{0}\right) \\
& =\frac{e^{-\lambda-\mu}}{k!}(\lambda+\mu)^{k} .
\end{aligned}
$$

The bracketed sum in the second last line is just the binomial expansion of $(\lambda+\mu)^{k}$.

Remark. How do you interpret the notation in the last calculation when $k=0$ ?
I always feel slightly awkward about a contribution from $k-1$ if $k=0$.
There is a sneakier way to calculate $\mathbb{E} X^{m}$ for $m=1,2, \ldots$ when $X$ has a Poisson $(\lambda)$ distribution. Code the whole distribution into a function (the probability generating function) of a dummy variable $s$ :

$$
g(s):=\mathbb{E} s^{X}=\sum_{k \geq 0} s^{k} e^{-\lambda} \frac{\lambda^{k}}{k!}=e^{-\lambda} \sum_{k \geq 0} \frac{(s \lambda)^{k}}{k!}=e^{-\lambda} e^{\lambda s} .
$$

Given $g$, the individual probabilities $\mathbb{P}\{X=k\}$ could be recovered by expanding the function as a power series in $s$.

Other facts about the distribution can also be obtained from $g$. For example,

$$
\frac{d}{d s} g(s)=\lim _{h \rightarrow 0} \mathbb{E}\left(\frac{(s+h)^{X}-s^{X}}{h}\right)=\mathbb{E} \frac{\partial}{\partial s} s^{X}=\mathbb{E} X s^{X-1}
$$

and, by direct calculation, $g^{\prime}(s)=e^{-\lambda} \lambda e^{\lambda s}$. Put $s=1$ in both expressions to deduce that $\mathbb{E} X=g^{\prime}(1)=\lambda$.

Similarly, repeated differentiation inside the expectation sign gives

$$
g^{(m)}(s)=\frac{\partial^{m}}{\partial s^{m}} \mathbb{E}\left(s^{X}\right)=\mathbb{E}\left(X(X-1) \ldots(X-m+1) s^{X-m}\right),
$$

and direct differentiation of $g$ gives $g^{(m)}(s)=e^{-\lambda} \lambda^{m} e^{\lambda s}$. Again put $s=1$ to deduce that

$$
\lambda^{m}=g^{(m)}(1)=\mathbb{E}(X(X-1) \ldots(X-m+1)) \quad \text { for } m=1,2, \ldots
$$

## Example 2

Suppose $n$ letters are placed at random into $n$ envelopes, one letter per envelope. The total number of correct matches, $S$, can be written as a sum $X_{1}+\cdots+X_{n}$ of indicators,

$$
X_{i}= \begin{cases}1 & \text { if letter } i \text { is placed in envelope } i, \\ 0 & \text { otherwise }\end{cases}
$$

The $X_{i}$ are dependent on each other. For example, symmetry implies that

$$
p_{i}=\mathbb{P}\left\{X_{i}=1\right\}=1 / n \quad \text { for each } i
$$

and

$$
\mathbb{P}\left\{X_{i}=1 \mid X_{1}=X_{2}=\cdots=X_{i-1}=1\right\}=\frac{1}{n-i+1}
$$

I could eliminate the dependence by relaxing the requirement of only one letter per envelope. The number of letters placed in the correct envelope (possibly together with other, incorrect letters) would then have a $\operatorname{Bin}(n, 1 / n)$ distribution, which is approximated by Poisson(1) if $n$ is large.

We can get some supporting evidence for $S$ having something close to a Poisson(1) distribution under the original assumption (one letter per envelope) by calculating some moments.

$$
\mathbb{E} S=\sum_{i \leq n} \mathbb{E} X_{i}=n \mathbb{P}\left\{X_{i}=1\right\}=1
$$

and

$$
\begin{aligned}
\mathbb{E} S^{2} & =\mathbb{E}\left(X_{1}^{2}+\cdots+X_{n}^{2}+2 \sum_{i<j} X_{i} X_{j}\right) \\
& =n \mathbb{E} X_{1}^{2}+2\binom{n}{2} \mathbb{E} X_{1} X_{2} \quad \text { by symmetry } \\
& =n \mathbb{P}\left\{X_{1}=1\right\}+\left(n^{2}-n\right) \mathbb{P}\left\{X_{1}=1, X_{2}=1\right\} \\
& =\left(n \times \frac{1}{n}\right)+\left(n^{2}-n\right) \times \frac{1}{n(n-1)} \\
& =2 .
\end{aligned}
$$

Thus $\operatorname{var}(S)=\mathbb{E} S^{2}-(\mathbb{E} S)^{2}=1$. Compare with Example $<1>$, which gives $\mathbb{E} Y=1$ and $\operatorname{var}(Y)=1$ for a $Y$ distributed Poisson(1).

Using the method of inclusion and exclusion, it is possible (Feller, 1968, Chapter 4) to calculate the exact distribution of the number of correct matches,

$$
\mathbb{P}\{S=k\}=\frac{1}{k!}\left(1-\frac{1}{1!}+\frac{1}{2!}-\frac{1}{3!}-\cdots \pm \frac{1}{(n-k)!}\right) \quad \text { for } k=0,1, \ldots, n .
$$

For fixed $k$, as $n \rightarrow \infty$ the probability converges to

$$
\frac{1}{k!}\left(1-1+\frac{1}{2!}-\frac{1}{3!}-\ldots\right)=\frac{e^{-1}}{k!}
$$

which is the probability that $Y=k$ if $Y$ has a Poisson(1) distribution.
The Chen-Stein method is also effective in this problem. I claim that it is intuitively clear (although a rigorous proof might be tricky) that the $X_{i}$ 's are positively associated:

$$
\mathbb{P}\left\{S_{-i} \geq k \mid X_{i}=1\right\} \geq \mathbb{P}\left\{S_{-i} \geq k \mid X_{i}=0\right\} \quad \text { for each } i \text { and each } k \in \mathbb{N}_{0} .
$$

I feel that if $X_{i}=1$, then it is more likely for the other letters to find their matching envelopes than if $X_{i}=0$, which makes things harder by filling one of the envelopes with the incorrect letter $i$. Positive association gives

$$
\frac{1}{2} \sum_{k \geq 0}\left|\mathbb{P}\{S=k\}-e^{-\lambda} \frac{\lambda^{k}}{k!}\right| \leq 2 \sum_{i=1}^{n} p_{i}^{2}+\operatorname{var}(S)-1=2 / n
$$

As $n$ gets large, the distribution of $S$ does get close to the Poisson(1) in the strong, total variation sense. However, it is possible (see Barbour et al. (1992), page 73) to get a better bound by working directly from ( $\star$ ).

## Appendix: The Chen-Stein method for the matching problem

You might actually find the argument leading to the final bound of Example $<2>$ more enlightening than the condensed exposition that follows. In any case, you can safely stop reading this chapter right now without suffering major probabilistic deprivation.

You were warned.
Consider once more the matching problem described in Example $<2>$. Use the Chen-Stein method to establish the approximation

$$
\mathbb{P}\{S=k\} \approx \frac{e^{-1}}{k!} \quad \text { for } k=0,1,2, \ldots
$$

The starting point is a curious connection between the Poisson(1) and the function $g(\cdot)$ defined by $g(0)=0$ and

$$
g(j)=\int_{0}^{1} e^{-t} t^{j-1} d t \quad \text { for } j=1,2, \ldots
$$

Notice that $0 \leq g(j) \leq 1$ for all $j$. Also, integration by parts shows that

$$
g(j+1)=j g(j)-e^{-1} \quad \text { for } j=1,2, \ldots
$$

and direct calculation gives

$$
g(1)=1-e^{-1}
$$

More succinctly,

$$
g(j+1)-j g(j)=1\{j=0\}-e^{-1} \quad \text { for } j=0,1, \ldots
$$

Actually the definition of $g(0)$ has no effect on the validity of the assertion when $j=0$; you could give $g(0)$ any value you liked.

Suppose $Y$ has a Poisson(1) distribution. Substitute $Y$ for $j$ in $<3\rangle$, then take expectations to get

$$
\mathbb{E}(g(Y+1)-Y g(Y))=\mathbb{E} 1\{Y=0\}-e^{-1}=\mathbb{P}\{Y=0\}-e^{-1}=0 .
$$

A similar calculation with $S$ in place of $Y$ gives

$$
\mathbb{P}\{S=0\}-e^{-1}=\mathbb{E}(g(S+1)-S g(S))
$$

If we can show that the right-hand side is close to zero then we will have

$$
\mathbb{P}\{S=0\} \approx e^{-1}
$$

which is the desired Poisson approximation for $\mathbb{P}\{S=k\}$ when $k=0$. A simple symmetry argument will then give the approximation for other $k$ values.

There is a beautiful probabilistic trick for approximating the right-hand side of $<4\rangle$. Write the $S g(S)$ contribution as

$$
\mathbb{E} S g(S)=\mathbb{E} \sum_{i=1}^{n} X_{i} g(S)=\sum_{i=1}^{n} \mathbb{E} X_{i} g(S)=n \mathbb{E} X_{1} g(S)
$$

The trick consists of a special two-step method for allocating letters at random to envelopes, which initially gives letter 1 a special role.
(i) (1) Put letter 1 in envelope 1, then allocate letters $2, \ldots, n$ to envelopes $2, \ldots, n$ in random order, one letter per envelope. Write $1+Z$ for the total number of matches of letters to correct envelopes. (The 1 comes from the forced matching of letter 1 and envelope 1.) Write $Y_{j}$ for the letter that goes into envelope $j$. Notice that $\mathbb{E} Z=1$, as shown in Example $<2>$.
(ii) (2) Choose an envelope $R$ at random (probability $1 / n$ for each envelope), then swap letter 1 with the letter in the chosen envelope.

Notice that $X_{1}$ is independent of $Z$, because of step 2. Indeed,

$$
\mathbb{P}\left\{X_{1}=1 \mid Z=k\right\}=\mathbb{P}\{R=1 \mid Z=k\}=1 / n \quad \text { for each } k .
$$

Notice also that

$$
S= \begin{cases}1+Z & \text { if } R=1 \\ Z-1 & \text { if } R \geq 2 \text { and } Y_{R}=R \\ Z & \text { if } R \geq 2 \text { and } Y_{R} \neq R\end{cases}
$$

Thus

$$
\begin{aligned}
\mathbb{P}\{S \neq Z \mid Z=k\} & =\mathbb{P}\{R=1\}+\sum j \geq 2 \mathbb{P}\left\{R=j, Y_{j}=j \mid Z=k\right\} \\
& =\frac{1}{n}+\frac{1}{n} \sum j \geq 2 \mathbb{P}\left\{Y_{j}=j \mid Z=k\right\} \\
& =\frac{k+1}{n}
\end{aligned}
$$

and

$$
\mathbb{P}\{S \neq Z\}=\sum_{k} \frac{k+1}{n} \mathbb{P}\{Z=k\}=\frac{\mathbb{E} Z+1}{n}=\frac{2}{n} .
$$

That is, the construction gives $S=Z$ with high probability.
From the fact that when $X_{1}=1$ (that is, $R=1$ ) we have $S=Z+1$, deduce that

$$
\begin{array}{rlrl}
\mathbb{E} S g(S) & =n \mathbb{E} X_{1} g(S) \quad \text { by } \quad<5> \\
& =n \mathbb{E} X_{1} g(1+Z) \quad \text { by }<6> \\
& =n \mathbb{E} X_{1} \mathbb{E} g(1+Z) \quad \text { by independence of } X_{1} \text { and } Z \\
& =\mathbb{E} g(1+Z) &
\end{array}
$$

Thus the right-hand side of $\langle 4\rangle$ equals $\mathbb{E}(g(S+1)-g(Z+1))$. On the event $\{S=Z\}$ the two terms cancel; on the event $\{S \neq Z\}$, the difference $g(S+1)-g(Z+1)$ lies between $\pm 1$ because $0 \leq g(j) \leq 1$ for $j=1,2, \ldots$. Combining these two contributions, we get

$$
|\mathbb{P}(g(S+1)-g(Z+1))| \leq 1 \times \mathbb{P}\{S \neq Z\} \leq \frac{2}{n}
$$

and

$$
\left|\mathbb{P}\{S=0\}-e^{-1}\right|=|\mathbb{P}(g(S+1)-S g(S))| \leq 2 / n
$$

The exact expression for $\mathbb{P}\{S=0\}$ from ( $\star$ ) shows that $2 / n$ greatly overestimates the error of approximation, but at least it tends to zero as $n$ gets large.

After all that work to justify the Poisson approximation to $\mathbb{P}\{S=k\}$ for $k=0$, you might be forgiven for shrinking from the prospect of extending the approximation to larger $k$. Fear not! The worst is over.

For $k=1,2, \ldots$ the event $\{S=k\}$ specifies exactly $k$ matches. There are $\binom{n}{k}$ choices for the matching envelopes. By symmetry, the probability of matches only in a particular set of $k$ envelopes is the same for each specific choice of the set of $k$ envelopes. It follows that

$$
\mathbb{P}\{S=k\}=\binom{n}{k} \mathbb{P}\{\text { envelopes } 1, \ldots, k \text { match; the rest don't }\}
$$

The probability of getting matches in envelopes $1, \ldots, k$ equals

$$
\frac{1}{n(n-1) \ldots(n-k+1)} .
$$

The conditional probability

$$
\mathbb{P}\{\text { envelopes } k+1, \ldots, n \text { don't match } \mid \text { envelopes } 1, \ldots, k \text { match }\}
$$

is equal to the probability of zero matches when $n-k$ letters are placed at random into their envelopes. If $n$ is much larger than $k$, this probability is close to $e^{-1}$, as shown above. Thus

$$
\mathbb{P}\{S=k\} \approx \frac{n!}{k!(n-k)!} \frac{1}{n(n-1)(n-2) \ldots(n-k+1)} e^{-1}=\frac{e^{-1}}{k!} .
$$

More formally, for each fixed $k$,

$$
\mathbb{P}\{S=k\} \rightarrow \frac{e^{-1}}{k!}=\mathbb{P}\{Y=k\} \quad \text { as } n \rightarrow \infty,
$$

where $Y$ has the Poisson(1) distribution.

## Chapter 10

## Poisson processes

The Binomial distribution and the geometric distribution describe the behavior of two random variables derived from the random mechanism that I have called coin tossing. The name coin tossing describes the whole mechanism; the names Binomial and geometric refer to particular aspects of that mechanism. If we increase the tossing rate to $n$ tosses per second and decrease the probability of heads to a small $p$, while keeping the expected number of heads per second fixed at $\lambda=n p$, the number of heads in a $t$ second interval will have approximately a $\operatorname{Bin}(n t, p)$ distribution, which is close to the Poisson $(\lambda t)$. Also, the numbers of heads tossed during disjoint time intervals will still be independent random variables. In the limit, as $n \rightarrow \infty$, we get an idealization called a Poisson process.

> Remark. The double use of the name Poisson is unfortunate. Much confusion would be avoided if we all agreed to refer to the mechanism as "idealizedvery-fast-coin-tossing", or some such. Then the Poisson distribution would have the same relationship to idealized-very-fast-coin-tossing as the Binomial distribution has to coin-tossing. Conversely, I could create more confusion by renaming coin tossing as "the binomial process". Neither suggestion is likely to be adopted, so you should just get used to having two closely related objects with the name Poisson.

Definition. A Poisson process with rate $\lambda$ on $[0, \infty)$ is a random mechanism that generates "points" strung out along $[0, \infty)$ in such a way that
(i) the number of points landing in any subinterval of length $t$ is a random variable with a Poisson $(\lambda t)$ distribution
(ii) the numbers of points landing in disjoint (= non-overlapping) intervals are independent random variables.

Note that, for a very short interval of length $\delta$, the number of points $X$ in the interval has a Poisson $(\lambda \delta)$ distribution, with

$$
\begin{aligned}
& \mathbb{P}\{X=0\}=e^{-\lambda \delta}=1-\lambda \delta+\text { terms of order } \delta^{2} \text { or smaller } \\
& \mathbb{P}\{X=1\}=\lambda \delta e^{-\lambda \delta}=\lambda \delta+\text { terms of order } \delta^{2} \text { or smaller } \\
& \mathbb{P}\{X \geq 2\}=1-e^{-\lambda \delta}-\lambda \delta e^{-\lambda \delta}=\text { quantity of order } \delta^{2} .
\end{aligned}
$$

When we pass to the idealized mechanism of points generated in continuous time, several awkward details of discrete-time coin tossing disappear.

It is easier to remember the distribution if we rescale the process, defining $T_{k}=$ $\lambda W_{k}$. The new $T_{k}$ has a continuous distribution with a $\operatorname{gamma}(k)$ density,

$$
f_{k}(t)=\frac{t^{k-1} e^{-t}}{(k-1)!} \mathbb{I}\{t>0\}
$$

Remark. Notice that $g_{k}=f_{k}$ when $\lambda=1$. That is, $T_{k}$ is the waiting time to the $k$ th point for a Poisson process with rate 1. Put another way, we can generate a Poisson process with rate $\lambda$ by taking the points appearing at times $0<T_{1}<T_{2}<T_{3}<\ldots$ from a Poisson process with rate 1 , then rescaling to produce a new process with points at

$$
0<\frac{T_{1}}{\lambda}<\frac{T_{2}}{\lambda}<\frac{T_{3}}{\lambda}<\ldots
$$

You could verify this assertion by checking the two defining properties for a Poisson process with rate $\lambda$. Doesn't it makes sense that, as $\lambda$ gets bigger, the points appear more rapidly?

More generally, for each $\alpha>0$,

$$
f_{\alpha}(t)=\frac{t^{\alpha-1} e^{-t}}{\Gamma(\alpha)} \mathbb{I}\{t>0\}
$$

is called the $\operatorname{gamma}(\alpha)$ density. The scaling constant, $\Gamma(\alpha)$, which ensures that the density integrates to one, is given by

$$
\Gamma(\alpha)=\int_{0}^{\infty} x^{\alpha-1} e^{-x} d x \quad \text { for each } \alpha>0
$$

The function $\Gamma(\cdot)$ is called the gamma function. Don't confuse the gamma density (or the gamma distribution that it defines) with the gamma function.
$<2>\quad$ Example. Facts about the gamma function: $\Gamma(k)=(k-1)$ ! for $k=1,2, \ldots$, and $\Gamma(1 / 2)=\sqrt{\pi}$.

The change of variable used in Example $<2>$ to prove $\Gamma(1 / 2)=\sqrt{\pi}$ is essentially the same piece of mathematics as the calculation on HW6 used to find the density for the distribution of $Y=Z^{2} / 2$ when $Z \sim N(0,1)$. The random variable $Y$ has a gamma ( $1 / 2$ ) distribution.

Example. Moments of the gamma distribution

The special case of the gamma distribution when the parameter $\alpha$ equals 1 is called the (standard) exponential distribution, with density $f_{1}(t)=e^{-t}$ for $t>0$, and zero elsewhere. From Example $<3>$, if $T_{1}$ has a standard exponential distribution then $\mathbb{E} T_{1}=1$. The waiting time $W_{1}$ to the first point in a Poisson process with rate $\lambda$ has the same distribution as $T_{1} / \lambda$, that is, a continuous distribution with density $\lambda e^{-\lambda t}$ for $t>0$, an exponential distribution with expected value $1 / \lambda$. Don't confuse the exponential density (or the exponential distribution that it defines) with the exponential function.

Notice the parallels between the negative binomial distribution (in discrete time) and the gamma distribution (in continuous time). Each distribution corresponds to the waiting time to the $k$ th occurrence of something, for various values of $k$. The negative binomial (see HW6) can be written as a sum of independent random variables, each with a geometric distribution. The $\operatorname{gamma}(k)$ can be written as a sum of $k$ independent random variables,

$$
T_{k}=T_{1}+\left(T_{2}-T_{1}\right)+\left(T_{3}-T_{2}\right)+\cdots+\left(T_{k}-T_{k-1}\right),
$$

each with a standard exponential distribution. (For a Poisson process, the independence between the counts in disjoint intervals ensures that the mechanism determining the time $W_{2}-W_{1}$ between the first and the second points is just another Poisson process started off at time $W_{1}$. And so on.) The times between points in a Poisson process are independent, exponentially distributed random variables.

Poisson Processes can also be defined for sets other than the half-line.
Example. A Poisson Process in two dimensions.

## Things to remember

Analogies between coin tossing, as a discrete time mechanism, and the Poisson process, as a continuous time mechanism:

| DISCRETE TIME | $\leftrightarrow$ | CONTINUOUS TIME |
| :--- | ---: | ---: |
| coin tossing, prob $p$ of heads | $\leftrightarrow$ | Poisson process with rate $\lambda$ |

## Examples for Chapter 10

## Example 1

Let $W_{k}$ denote the waiting time to the $k$ th point in a Poisson process on $[0, \infty)$ with rate $\lambda$. It has a continuous distribution, whose density $g_{k}$ we can find by an argument similar to the one used in Chapter 6 to find the distribution of an order statistic for a sample from the $\operatorname{Uniform}(0,1)$.

For a given $w>0$ and small $\delta>0$, write $M$ for the number of points landing in the interval $[0, w)$, and $N$ for the number of points landing in the interval $[w, w+\delta]$. From the definition of a Poisson process, $M$ and $N$ are independent random variables with

$$
M \sim \operatorname{Poisson}(\lambda w) \quad \text { AND } \quad N \sim \operatorname{Poisson}(\lambda \delta)
$$

To have $W_{k}$ lie in the interval $[w, w+\delta]$ we must have $N \geq 1$. When $N=1$, we need exactly $k-1$ points to land in $[0, w)$. Thus

$$
\mathbb{P}\left\{w \leq W_{k} \leq w+\delta\right\}=\mathbb{P}\{M=k-1, N=1\}+\mathbb{P}\left\{w \leq W_{k} \leq w+\delta, N \geq 2\right\}
$$

The second term on the right-hand side is of order $\delta^{2}$. Independence of $M$ and $N$ lets us factorize the contribution from $N=1$ into

$$
\begin{aligned}
\mathbb{P}\{M=k-1\} \mathbb{P}\{N=1\} & =\frac{e^{-\lambda w}(\lambda w)^{k-1}}{(k-1)!} \frac{e^{-\lambda \delta}(\lambda \delta)^{1}}{1!} \\
& =\frac{e^{-\lambda w} \lambda^{k-1} w^{k-1}}{(k-1)!}(\lambda \delta+\text { smaller order terms }),
\end{aligned}
$$

Thus

$$
\mathbb{P}\left\{w \leq W_{k} \leq w+\delta\right\}=\frac{e^{-\lambda w} \lambda^{k} w^{k-1}}{(k-1)!} \delta+\text { smaller order terms },
$$

which makes

$$
g_{k}(w)=\frac{e^{-\lambda w} \lambda^{k} w^{k-1}}{(k-1)!} \mathbb{I}\{w>0\}
$$

the density function for $W_{k}$.

## Example 2

The gamma function is defined for $\alpha>0$ by

$$
\Gamma(\alpha)=\int_{0}^{\infty} x^{\alpha-1} e^{-x} d x
$$

By direct integration, $\Gamma(1)=\int_{0}^{\infty} e^{-x} d x=1$. Also, a change of variable $y=\sqrt{2 x}$ gives

$$
\begin{aligned}
\Gamma(1 / 2) & =\int_{0}^{\infty} x^{-1 / 2} e^{-x} d x \\
& =\int_{0}^{\infty} \sqrt{2} e^{-y^{2} / 2} d y \\
& =\frac{\sqrt{2}}{2} \frac{\sqrt{2 \pi}}{\sqrt{2 \pi}} \int_{-\infty}^{\infty} e^{-y^{2} / 2} d y \\
& =\sqrt{\pi} \quad \text { cf. integral of } N(0,1) \text { density. }
\end{aligned}
$$

For each $\alpha>0$, an integration by parts gives

$$
\begin{aligned}
\Gamma(\alpha+1) & =\int_{0}^{\infty} x^{\alpha} e^{-x} d x \\
& =\left[-x^{\alpha} e^{-x}\right]_{0}^{\infty}+\alpha \int_{0}^{\infty} x^{\alpha-1} e^{-x} d x \\
& =\alpha \Gamma(\alpha) .
\end{aligned}
$$

Repeated appeals to the same formula, for $\alpha>0$ and each positive integer $m$, give

$$
\begin{equation*}
\Gamma(\alpha+m)=(\alpha+m-1)(\alpha+m-2) \ldots(\alpha) \Gamma(\alpha) . \tag{*}
\end{equation*}
$$

In particular,

$$
\Gamma(k)=(k-1)(k-2)(k-3) \ldots(2)(1) \Gamma(1)=(k-1)!\quad \text { for } k=1,2, \ldots .
$$

## Example 3

For parameter value $\alpha>0$, the gamma $(\alpha)$ distribution is defined by its density

$$
f_{\alpha}(t)= \begin{cases}t^{\alpha-1} e^{-t} / \Gamma(\alpha) & \text { for } t>0 \\ 0 & \text { otherwise }\end{cases}
$$

If a random variable $T$ has a gamma $(\alpha)$ distribution then, for each positive integer $m$,

$$
\begin{aligned}
\mathbb{E} T^{m} & =\int_{0}^{\infty} t^{m} f_{\alpha}(t) d t \\
& =\int_{0}^{\infty} \frac{t^{m} t^{\alpha-1} e^{-t}}{\Gamma(\alpha)} d t \\
& =\frac{\Gamma(\alpha+m)}{\Gamma(\alpha)} \\
& =(\alpha+m-1)(\alpha+m-2) \ldots(\alpha) \quad \text { by equality }(*) \text { in Example }<2>.
\end{aligned}
$$

In particular, $\mathbb{E} T=\alpha$ and

$$
\operatorname{var}(T)=\mathbb{E}\left(T^{2}\right)-(\mathbb{E} T)^{2}=(\alpha+1) \alpha-\alpha^{2}=\alpha
$$

## Example 4

A Poisson process with rate $\lambda$ on $\mathbb{R}^{2}$ is a random mechanism that generates "points" in the plane in such a way that
(i) the number of points landing in any region of area $A$ is a random variable with a Poisson $(\lambda A)$ distribution
(ii) the numbers of points landing in disjoint regions are independent random variables.

Suppose mold spores are distributed across the plane as a Poisson process with intensity $\lambda$. Around each spore, a circular moldy patch of radius $r$ forms. Let $S$ be some bounded region. Find the expected proportion of the area of $S$ that is covered by mold.

Write $\mathbf{x}=(x, y)$ for the typical point of $\mathbb{R}^{2}$. If $B$ is a subset of $\mathbb{R}^{2}$,

$$
\text { area of } S \cap B=\iint_{\mathbf{x} \in S} \mathbb{I}\{\mathbf{x} \in B\} d \mathbf{x}
$$

If $B$ is a random set then

$$
\mathbb{E}(\text { area of } S \cap B)=\iint_{\mathbf{x} \in S} \mathbb{E} \mathbb{I}\{\mathbf{x} \in B\} d \mathbf{x}=\iint_{\mathbf{x} \in S} \mathbb{P}\{\mathbf{x} \in B\} d \mathbf{x}
$$

If $B$ denotes the moldy region of the plane,

$$
\begin{aligned}
1-\mathbb{P}\{\mathbf{x} \in B\} & =\mathbb{P}\{\text { no spores land within a distance } r \text { of } \mathbf{x}\} \\
& =\mathbb{P}\{\text { no spores in circle of radius } r \text { around } \mathbf{x}\} \\
& =\exp \left(-\lambda \pi r^{2}\right)
\end{aligned}
$$

Notice that the probability does not depend on $\mathbf{x}$. Connsequently,
$\mathbb{E}($ area of $S \cap B)=\iint_{\mathbf{x} \in S} 1-\exp \left(-\lambda \pi r^{2}\right) d \mathbf{x}=\left(1-\exp \left(-\lambda \pi r^{2}\right)\right) \times$ area of $S$
The expected proportion of the area of $S$ that is covered by mold is $1-\exp \left(-\lambda \pi r^{2}\right)$.

## Addendum to Chapter 10

$<1>$ Example. Suppose an office receives two different types of inquiry: persons who walk in off the street, and persons who call by telephone. Suppose the two types of arrival are described by independent Poisson processes, with rate $\lambda_{w}$ for the walkins, and rate $\lambda_{c}$ for the callers. What is the distribution of the number of telephone calls received before the first walk-in customer?

Write $T$ for the arrival time of the first walk-in, and let $N$ be the number of calls in $[0, T)$. The time $T$ has a continuous distribution, with the exponential density $f(t)=\lambda_{w} e^{-\lambda_{w} t}$ for $t>0$. We need to calculate $\mathbb{P}\{N=i\}$ for $i=0,1,2, \ldots$. Condition on $T$ :

$$
\mathbb{P}\{N=i\}=\int_{0}^{\infty} \mathbb{P}\{N=i \mid T=t\} f(t) d t
$$

The conditional distribution of $N$ is affected by the walk-in process only insofar as that process determines the length of the time interval over which $N$ counts. Given $T=t$, the random variable $N$ has a Poisson $\left(\lambda_{c} t\right)$ conditional distribution. Thus

$$
\begin{aligned}
\mathbb{P}\{N=i\} & =\int_{0}^{\infty} \frac{e^{-\lambda_{c} t}\left(\lambda_{c} t\right)^{i}}{i!} \lambda_{w} e^{-\lambda_{w} t} d t \\
& =\lambda_{w} \frac{\lambda_{c}^{i}}{i!} \int_{0}^{\infty}\left(\frac{x}{\lambda_{c}+\lambda_{w}}\right)^{i} e^{-x} \frac{d x}{\lambda_{c}+\lambda_{w}} \quad \text { putting } x=\left(\lambda_{c}+\lambda_{w}\right) t \\
& =\frac{\lambda_{w}}{\lambda_{c}+\lambda_{w}}\left(\frac{\lambda_{c}}{\lambda_{c}+\lambda_{w}}\right)^{i} \frac{1}{i!} \int_{0}^{\infty} x^{i} e^{-x} d x
\end{aligned}
$$

The $1 / i!$ and the last integral cancel. (Compare with $\Gamma(i+1)$.) Writing $p$ for $\lambda_{w} /\left(\lambda_{c}+\lambda_{w}\right)$ we have

$$
\mathbb{P}\{N=i\}=p(1-p)^{i} \quad \text { for } i=0,1,2, \ldots
$$

That is, $1+N$ has a geometric $(p)$ distribution. The random variable $N$ has the distribution of the number of tails tossed before the first head, for independent tosses of a coin that lands heads with probability $p$.

Such a clean result couldn't happen just by accident. HW9 will give you a neater way to explain how the geometric got into the Poisson process.

## Chapter 11

## Joint densities

Consider the general problem of describing probabilities involving two random variables, $X$ and $Y$. If both have discrete distributions, with $X$ taking values $x_{1}, x_{2}, \ldots$ and $Y$ taking values $y_{1}, y_{2}, \ldots$, then everything about the joint behavior of $X$ and $Y$ can be deduced from the set of probabilities

$$
\mathbb{P}\left\{X=x_{i}, Y=y_{j}\right\} \quad \text { for } i=1,2, \ldots \text { and } j=1,2, \ldots
$$

We have been working for some time with problems involving such pairs of random variables, but we have not needed to formalize the concept of a joint distribution. When both $X$ and $Y$ have continuous distributions, it becomes more important to have a systematic way to describe how one might calculate probabilities of the form $\mathbb{P}\{(X, Y) \in B\}$ for various subsets $B$ of the plane. For example, how could one calculate $\mathbb{P}\{X<Y\}$ or $\mathbb{P}\left\{X^{2}+Y^{2} \leq 9\right\}$ or $\mathbb{P}\{X+Y \leq 7\}$ ?

Definition. Say that random variables X and Y have a jointly continuous distribution with joint density function $f(\cdot, \cdot)$ if

$$
\mathbb{P}\{(X, Y) \in B\}=\iint_{B} f(x, y) d x d y
$$

for each subset $B$ of $\mathbb{R}^{2}$.
Remark. To avoid messy expressions in subscripts, I will sometimes write $\iint \mathbb{I}\{(x, y) \in B\} \ldots$ instead of $\iint_{B} \ldots$

The density function defines a surface, via the equation $z=f(x, y)$. The probability that the random point $(X, Y)$ lands in $B$ is equal to the volume of the "cylinder"

$$
\left\{(x, y, z) \in \mathbb{R}^{3}: 0 \leq z \leq f(x, y) \quad \text { and } \quad(x, y) \in B\right\}
$$

In particular, if $\Delta$ is small region in $\mathbb{R}^{2}$ around a point $\left(x_{0}, y_{0}\right)$ at which $f$ is continuous, the cylinder is close to a thin column with cross-section $\Delta$ and height $f\left(x_{0}, y_{0}\right)$, so that

$$
\mathbb{P}\{(X, Y) \in \Delta\}=(\text { area of } \Delta) f\left(x_{0}, y_{0}\right)+\text { smaller order terms. }
$$

More formally,

$$
\lim _{\Delta \downarrow\left\{x_{0}, y_{0}\right)} \frac{\mathbb{P}\{(X, Y) \in \Delta\}}{\text { area of } \Delta}=f\left(x_{0}, y_{0}\right) .
$$

The limit is taken as $\Delta$ shrinks to the point $\left(x_{0}, y_{0}\right)$.

Remark. For a rigorous treatment, $\Delta$ is not allowed to be too weirdly shaped. One can then show that the limit exists and equals $f\left(x_{0}, y_{0}\right)$ except for $\left(x_{0}, y_{0}\right)$ in a region with zero area.

To calculate $\mathbb{P}\{(X, Y) \in B\}$ for a larger region $B$, we could partition $B$ into small regions $\Delta_{1}, \Delta_{2}, \ldots$, then add up the contributions to the probability from each region: $\mathbb{P}\{(X, Y) \in B\}=\sum_{i} \mathbb{P}\left\{(X, Y) \in \Delta_{i}\right\}$. The sum is approximately equal to the volume of the entire region bounded by the surface and the plane $z=0$, and lying above the set $B$, a volume given precisely by the double integral. As we make the partitions finer, the errors of approximation go to zero. In the limit, $\mathbb{P}\{(X, Y) \in B\}$ is recovered as the double integral.

Apart from the replacement of single integrals by double integrals and the replacement of intervals of small length by regions of small area, the definition of a joint density is essentially the same as the definition for densities on the real line in Chapter 6.

To ensure that $\mathbb{P}\{(X, Y) \in B\}$ is nonnegative and that it equals one when $B$ is the whole of $\mathbb{R}^{2}$, we must require

$$
f \geq 0 \quad \text { and } \quad \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) d x d y=1
$$

The joint density for $(X, Y)$ includes information about the marginal distributions of the random variables. To see why, write $A \times \mathbb{R}$ for the subset $\left\{(x, y) \in \mathbb{R}^{2}: x \in A, y \in \mathbb{R}\right\}$ for a subset $A$ of the real line. Then

$$
\begin{aligned}
& \mathbb{P}\{X \in A\} \\
& \quad=\mathbb{P}\{(X, Y) \in A \times \mathbb{R}\} \\
& =\iint \mathbb{I}\{x \in A, y \in \mathbb{R}\} f(x, y) d x d y \\
& =\int_{-\infty}^{+\infty} \mathbb{I}\{x \in A\}\left(\int_{-\infty}^{+\infty} \mathbb{I}\{y \in \mathbb{R}\} f(x, y) d y\right) d x \\
& =\int_{-\infty}^{+\infty} \mathbb{I}\{x \in A\} h(x) d x \quad \text { where } h(x)=\int_{-\infty}^{+\infty} f(x, y) d y .
\end{aligned}
$$

It follows that $X$ has a continuous distribution with (marginal) density $h$. Similarly, $Y$ has a continuous distribution with (marginal) density $g(y)=\int_{-\infty}^{+\infty} f(x, y) d x$.

Remark. The word marginal is used here to distinguish the joint density for $(X, Y)$ from the individual densities $g$ and $h$.

When we wish to calculate a density, the small region $\Delta$ can be chosen in many ways-small rectangles, small disks, small blobs, and even small shapes that don't have any particular name - whatever suits the needs of a particular calculation.

Example. (Joint densities for independent random variables) Suppose $X$ has a continuous distribution with density $g$ and $Y$ has a continuous distribution with density $h$. Then $X$ and $Y$ are independent if and only if they have a jointly continuous distribution with joint density $f(x, y)=g(x) h(y)$ for all $(x, y) \in \mathbb{R}^{2}$.

When pairs of random variables are not independent it takes more work to find a joint density. The prototypical case, where new random variables are constructed as linear functions of random variables with a known joint density, illustrates a general method for deriving joint densities.
$<2>\quad$ Example. Suppose $X$ and $Y$ have a jointly continuous distribution with density function $f$. Define $S=X+Y$ and $T=X-Y$. Show that $(S, T)$ has a jointly continuous distribution with density $\psi(s, t)=\frac{1}{2} f\left(\frac{s+t}{2}, \frac{s-t}{2}\right)$.

For instance, suppose the $X$ and $Y$ from Example $<2>$ are independent and each is $N(0,1)$ distributed. From Example $<1>$, the joint density for $(X, Y)$ is

$$
f(x)=\frac{1}{2 \pi} \exp \left(\frac{1}{2}\left(x^{2}+y^{2}\right)\right) .
$$

The joint density for $S=X+Y$ and $T=X-Y$ is

$$
\begin{aligned}
\psi(s, t) & =\frac{1}{4 \pi} \exp \left(\frac{1}{8}\left((s+t)^{2}+(s-t)^{2}\right)\right) \\
& =\frac{1}{\sigma \sqrt{2 \pi}} \exp \left(-s^{2} /\left(2 \sigma^{2}\right)\right) \frac{1}{\sigma \sqrt{2 \pi}} \exp \left(-t^{2} /\left(2 \sigma^{2}\right)\right) \quad \text { where } \sigma^{2}=2
\end{aligned}
$$

It follows that $S$ and $T$ are independent, each with a $N(0,2)$ distribution.
Example $<2>$ also implies the convolution formula from Chapter 7. For if $X$ and $Y$ are independent, with densities $g$ and $h$, then their joint density is $f(x, y)=$ $g(x) h(y)$ and the joint density for $S=X+Y$ and $T=X-Y$ is

$$
\psi(s, t)=\frac{1}{2} h g\left(\frac{s+t}{2}\right) h\left(\frac{s-t}{2}\right)
$$

Integrate over $t$ to get the marginal density for $S$ :

$$
\begin{aligned}
\int_{-\infty}^{+\infty} \psi(s, t) d t & =\int_{-\infty}^{+\infty} \frac{1}{2} g\left(\frac{s+t}{2}\right) h\left(\frac{s-t}{2}\right) d t \\
& =\int_{-\infty}^{+\infty} g(x) h(s-x) d x \quad \text { putting } x=(s+t) / 2
\end{aligned}
$$

The argument for general linear combinations is slightly more complicated. The next Example could be skipped.
$<3>\quad$ Example. Suppose $X$ and $Y$ have a jointly continuous distribution with joint density $f(x, y)$. For constants $a, b, c, d$, define $U=a X+b Y$ and $V=c X+d Y$. Find the joint density function $\psi(u, v)$ for $(U, V)$, under the assumption that the quantity $\kappa=a d-b c$ is nonzero.

The method used in Example $<3>$, for linear transformations, extends to give a good approximation for more general smooth transformations when applied to small regions. Densities describe the behaviour of distributions in small regions; in small regions smooth transformations are approximately linear; the density formula for linear transformations gives a good approximation to the density for smooth transformations in small regions.

For example, from class you know that for independent random variables $X$ and $Y$ with $X \sim \operatorname{gamma}(\alpha)$ and $Y \sim \operatorname{gamma}(\beta)$, we have $X+Y \sim \operatorname{gamma}(\alpha+\beta)$. The next Example provides an alternative way to derive this results, plus a little more.
$<4>\quad$ Example. Suppose $X$ and $Y$ are independent random variables, with $X \sim \operatorname{gamma}(\alpha)$ and $Y \sim \operatorname{gamma}(\beta)$. Show that the random variables $U=X /(X+Y)$ and $V=X+Y$ are independent, with $U \sim \operatorname{beta}(\alpha, \beta)$ and $V \sim \operatorname{gamma}(\alpha+\beta)$.

The conclusion about $X+Y$ from Example $<4>$ extends to sums of more than two independent random variables, each with a gamma distribution. The result has a particularly important special case, involving the sums of squares of independent standard normals.
$<5>\quad$ Example. Sums of independent gamma random variables.

## Examples for Chapter 11

## Example 1

(Joint densities for independent random variables) Suppose $X$ has a continuous distribution with density $g$ and $Y$ has a continuous distribution with density $h$. Then $X$ and $Y$ are independent if and only if they have a jointly continuous distribution with joint density $f(x, y)=g(x) h(y)$ for all $(x, y) \in \mathbb{R}^{2}$.

When $X$ has density $g(x)$ and $Y$ has density $h(y)$, and $X$ is independent of $Y$, the joint density is particularly easy to calculate. Let $\Delta$ be a small rectangle with one corner at $\left(x_{0}, y_{0}\right)$ and small sides of length $\delta>0$ and $\epsilon>0$,

$$
\Delta=\left\{(x, y) \in \mathbb{R}^{2}: x_{0} \leq x \leq x_{0}+\delta, y_{0} \leq y \leq y_{0}+\epsilon\right\} .
$$

By independence,

$$
\begin{aligned}
\mathbb{P}\{(X, Y) \in \Delta\} & =\mathbb{P}\left\{x_{0} \leq X \leq x_{0}+\delta\right\} \mathbb{P}\left\{y_{0} \leq Y \leq y_{0}+\epsilon\right\} \\
& \approx \delta g\left(x_{0}\right) \epsilon h\left(y_{0}\right)=(\text { area of } \Delta) \times g\left(x_{0}\right) h\left(y_{0}\right) .
\end{aligned}
$$

Thus $X$ and $Y$ have a joint density that takes the value $f\left(x_{0}, y_{0}\right)=g\left(x_{0}\right) h\left(y_{0}\right)$ at $\left(x_{0}, y_{0}\right)$.

Conversely, if $X$ and $Y$ have a joint density $f$ that factorizes, $f(x, y)=g(x) h(y)$, then, for some constant $K$, for each pair of subsets $C, D$ of the real line,

$$
\begin{aligned}
\mathbb{P}\{X \in C, Y \in D\} & =\iint \mathbb{I}\{x \in C, y \in D\} f(x, y) d x d y \\
& =\iint \mathbb{I}\{x \in C\} \mathbb{I}\{y \in D\} g(x) h(y) d x d y \\
& =\left(\int \mathbb{I}\{x \in C\} g(x) d x\right)\left(\int \mathbb{I}\{y \in D\} h(y) d y\right)
\end{aligned}
$$

In particular, if we take $C=D=\mathbb{R}$ then we get

$$
\int_{-\infty}^{\infty} g(x) d x=K \quad \text { AND } \quad \int_{-\infty}^{\infty} h(y) d y=1 / K
$$

If we take only $D=\mathbb{R}$ we get

$$
\mathbb{P}\{X \in C\}=\mathbb{P}\{X \in C, Y \in \mathbb{R}\}=\int_{C} g(x) / K d x
$$

from which it follows that $g(x) / K$ is the marginal density for $X$. Similarly, $K h(y)$ is the marginal density for $Y$. Moreover, provided $\mathbb{P}\{Y \in D\} \neq 0$,

$$
\mathbb{P}\{X \in C \mid Y \in D\}=\frac{\mathbb{P}\{X \in C, Y \in D\}}{\mathbb{P}\{Y \in D\}}=\frac{\mathbb{P}\{X \in C\} \mathbb{P}\{Y \in D\}}{\mathbb{P}\{Y \in D\}}=\mathbb{P}\{X \in C\} .
$$

The random variables $X$ and $Y$ are independent.
Of course, if we know that $g$ and $h$ are the marginal densities then we have $K=$ 1. The argument in the previous paragraph actually shows that any factorization $f(x, y)=g(x) h(y)$ of a joint density (even if we do not know that the factors are the marginal densities) implies independence.

## Example 2

Suppose $X$ and $Y$ have a jointly continuous distribution with density function f. Define $S=X+Y$ and $T=X-Y$. Show that $(S, T)$ has a jointly continuous distribution with density $g(s, t)=\frac{1}{2} f\left(\frac{s+t}{2}, \frac{s-t}{2}\right)$.

Consider a small ball $\Delta$ of radius $\epsilon$ centered at a point $\left(s_{0}, t_{0}\right)$ in the plane. The area of $\Delta$ equals $\pi \epsilon^{2}$. The point $\left(s_{0}, t_{0}\right)$ in the ( $S, T$ )-plane (the region where $(S, T)$ takes its values) corresponds to the point $\left(x_{0}, y_{0}\right)$ in the ( $X, Y$ )-plane for which $s_{0}=x_{0}+y+0$ and $t_{0}=x_{0}-y_{0}$. That is, $x_{0}=\left(s_{0}+t_{0}\right) / 2$ and $y_{0}=\left(s_{0}-t_{0}\right) / 2$.

We need to identify $\{(S, T) \in \Delta\}$ with some set $\{(X, Y) \in D\}$.

By great luck (or by a clever choice for $\Delta$ ) the region $D$ in the $(X, Y)$-plane turns out to be another ball:

$$
\begin{aligned}
\{(S, T) \in \Delta\} & =\left\{\left(S-s_{0}\right)^{2}+\left(T-t_{0}\right)^{2} \leq \epsilon^{2}\right\} \\
& =\left\{\left(X+Y-x_{0}-y_{0}\right)^{2}+\left(X-Y-x_{0}+y_{0}\right)^{2} \leq \epsilon^{2}\right\} \\
& =\left\{2\left(X-x_{0}\right)^{2}+2\left(Y-y_{0}\right)^{2} \leq \epsilon^{2}\right\}
\end{aligned}
$$

(Notice the cancellation of $\left(X-x_{0}\right)\left(Y-y_{0}\right)$ terms.) That is $D$ is a ball of radius $\epsilon / \sqrt{2}$ centered at $\left(x_{0}, y_{0}\right)$, with area $\pi \epsilon^{2} / 2$, which is half the area of $\Delta$. Now we can calculate.

$$
\begin{aligned}
\mathbb{P}\{(S, T) \in \Delta\} & =\mathbb{P}\{(X, Y) \in D\} \\
& \approx \text { area of } D \times f\left(x_{0}, y_{0}\right) \\
& =\frac{1}{2} \text { area of } \Delta \times f\left(\frac{s_{0}+t_{0}}{2}, \frac{s_{0}-t_{0}}{2}\right)
\end{aligned}
$$

It follows that $(S, T)$ has joint density $g(s, t)=\frac{1}{2} f\left(\frac{s+t}{2}, \frac{s-t}{2}\right)$.

## Example 3

(Can be skipped.) Suppose $X$ and $Y$ have a jointly continuous distribution with joint density $f(x, y)$. For constants $a, b, c, d$, define $U=a X+b Y$ and $V=c X+d Y$. Find the joint density function $\psi(u, v)$ for $(U, V)$, under the assumption that the quantity $\kappa=a d-b c$ is nonzero.

In matrix notation,

$$
(U, V)=(X, Y) A \quad \text { where } A=\left(\begin{array}{ll}
a & c \\
b & d
\end{array}\right) .
$$

Notice that $\operatorname{det} A=a d-b c=\kappa$. The assumption that $\kappa \neq 0$ ensures that $A$ has an inverse:

$$
A^{-1}=\frac{1}{\kappa}\left(\begin{array}{cc}
d & -c \\
-b & a
\end{array}\right)
$$

That is, if $(u, v)=(x, y) A$ then

$$
\frac{d u-b v}{\kappa}=x \quad \text { and } \quad \frac{-c u+a v}{\kappa}=y .
$$

Notice that $\operatorname{det}\left(A^{-1}\right)=1 / \kappa=1 /(\operatorname{det} A)$.
Consider a small rectangle $\Delta=\left\{u_{0} \leq u \leq u_{0}+\delta, v_{0} \leq v \leq v_{0}+\epsilon\right\}$, for $\left(u_{0}, v_{0}\right)$ in the $(U, V)$-plane and small, positive $\delta$ and $\epsilon$. The joint density function $\psi(u, v)$ is characterized by the property that

$$
\mathbb{P}\{(U, V) \in \Delta\} \approx \psi\left(u_{0}, v_{0}\right) \delta \epsilon
$$

The event $\{(U, V) \in \Delta\}$ is equal to some event $\{(X, Y) \in D\}$. The linear transformation $A^{-1}$ maps parallel straight lines in the $(U, V)$-plane into parallel straight lines in the $(X, Y)$-plane. The region $D$ must be a parallelogram. We have only to determine its vertices, which correspond to the four vertices of the rectangle $\Delta$. Define vectors $\alpha_{1}=(d,-c) / \kappa$ and $\alpha_{2}=(-b, a) / \kappa$, which correspond to the two rows of the matrix $A^{-1}$. Then $D$ has vertices:

$$
\begin{aligned}
\left(x_{0}, y_{0}\right) & =\left(u_{0}, v_{0}\right) A^{-1}=u_{0} \alpha_{1}+v_{0} \alpha_{2} \\
\left(x_{0}, y_{0}\right)+\delta \alpha_{1} & =\left(u_{0}+\delta, v_{0}\right) A^{-1}=\left(u_{0}+\delta\right) \alpha_{1}+v_{0} \alpha_{2} \\
\left(x_{0}, y_{0}\right)+\epsilon \alpha_{2} & =\left(u_{0}, v_{0}+\epsilon\right) A^{-1}=u_{0} \alpha_{1}+\left(v_{0}+\epsilon\right) \alpha_{2} \\
\left(x_{0}, y_{0}\right)+\delta \alpha_{1}+\epsilon \alpha_{2} & =\left(u_{0}+\delta, v_{0}+\epsilon\right) A^{-1}=\left(u_{0}+\delta\right) \alpha_{1}+\left(v_{0}+\epsilon\right) \alpha_{2}
\end{aligned}
$$

From the formula in the Appendix to this Chapter, the parallelogram $D$ has area equal to $\delta \epsilon$ times the absolute value of the determinant of the matrix with rows $\alpha_{1}$ and $\alpha_{2}$. That is,

$$
\text { area of } D=\delta \epsilon\left|\operatorname{det}\left(A^{-1}\right)\right|=\frac{\delta \epsilon}{|\operatorname{det} A|} \text {. }
$$

In summary: for small $\delta>0$ and $\epsilon>0$,

$$
\begin{aligned}
\psi\left(u_{0}, v_{0}\right) \delta \epsilon & \approx \mathbb{P}\{(U, V) \in \Delta\} \\
& =\mathbb{P}\{(X, Y) \in D\} \\
& \approx(\operatorname{area} \text { of } D) f\left(x_{0}, y_{0}\right) \\
& \approx \delta \epsilon f\left(x_{0}, y_{0}\right) /|\operatorname{det}(A)| .
\end{aligned}
$$

It follows that $(U, V)$ have joint density

$$
\psi(u, v)=\frac{1}{|\operatorname{det} A|} f(x, y) \quad \text { where }(x, y)=(u, v) A^{-1}
$$

On the right-hand side you should substitute $(d u-b v) / \kappa$ for $x$ and $(-c u+a v) / \kappa$ for $y$, in order to get an expresion involving only $u$ and $v$.

Remark. In effect, I have calculated a Jacobian by first principles.

## Example 4

Suppose $X$ and $Y$ are independent random variables, with $X \sim \operatorname{gamma}(\alpha)$ and $Y \sim$ gamma $(\beta)$. Show that the random variables $U=X /(X+Y)$ and $V=X+Y$ are independent, with $U \sim \operatorname{beta}(\alpha, \beta)$ and $V \sim \operatorname{gamma}(\alpha+\beta)$.

The random variables $X$ and $Y$ have marginal densities

$$
g(x)=x^{\alpha-1} e^{-x} \mathbb{I}\{x>0\} / \Gamma(\alpha) \quad \text { and } \quad h(y)=y^{\beta-1} e^{-y} \mathbb{I}\{y>0\} / \Gamma(\beta)
$$

From Example $<1>$, they have a jointly continuous distribution with joint density

$$
f(x, y)=g(x) h(y)=\frac{x^{\alpha-1} e^{-x} y^{\beta-1} e^{-y}}{\Gamma(\alpha) \Gamma(\beta)} \mathbb{I}\{x>0, y>0\} .
$$

We need to find the joint density function $\psi(u, v)$ for the random variables $U=X /(X+Y)$ and $V=X+Y$. The pair $(U, V)$ takes values in the strip defined by $\left\{(u, v) \in \mathbb{R}^{2}: 0<u<1,0<v<\infty\right\}$. The joint density function $\psi$ can be determined by considering corresponding points ( $x_{0}, y_{0}$ ) in the ( $x, y$ )-quadrant and ( $u_{0}, v_{0}$ ) in the $(u, v)$-strip for which

$$
u_{0}=x_{0} /\left(x_{0}+y_{0}\right) \quad \text { AND } \quad v_{0}=x_{0}+y_{0},
$$

that is,

$$
x_{0}=u_{0} v_{0} \quad \text { AND } \quad y_{0}=\left(1-u_{0}\right) v_{0}
$$

When $(U, V)$ lies near $\left(u_{0}, v_{0}\right)$ then $(X, Y)$ lies near $\left(x_{0}, y_{0}\right)=\left(u_{0} v_{0}, v_{0}\left(1-u_{0}\right)\right)$. More precisely, for small positive $\delta$ and $\epsilon$, there is a small region $D$ in the $(X, Y)$ quadrant corresponding to the small rectangle

$$
\Delta=\left\{(u, v): u_{0} \leq u \leq u_{0}+\delta, v_{0} \leq v \leq v_{0}+\epsilon\right\}
$$

in the $(U, V)$-strip. That is, $\{(U, V) \in \Delta\}=\{(X, Y) \in D\}$. The set $D$ is not a parallelogram but it is well approximated by one. For small perturbations, the map from $(u, v)$ to $(x, y)$ is approximately linear. First locate the points corresponding to the corners of $\Delta$, under the maps $x=u v$ and $y=v(1-u)$ :

$$
\begin{aligned}
\left(u_{0}+\delta, v_{0}\right) & \leftrightarrow\left(x_{0}, y_{0}\right)+\left(\delta v_{0},-\delta v_{0}\right) \\
\left(u_{0}, v_{0}+\epsilon\right) & \leftrightarrow\left(x_{0}, y_{0}\right)+\left(\epsilon u_{0}, \epsilon\left(1-u_{0}\right)\right) \\
\left(u_{0}+\delta, v_{0}+\epsilon\right) & \leftrightarrow\left(x_{0}, y_{0}\right)+\left(\delta v_{0}+\epsilon u_{0}+\delta \epsilon,-\delta v_{0}+\epsilon\left(1-u_{0}\right)-\delta \epsilon\right) \\
& =\left(x_{0}, y_{0}\right)+\left(\delta v_{0}+\epsilon u_{0},-\delta v_{0}+\epsilon\left(1-u_{0}\right)\right)+(\delta \epsilon,-\delta \epsilon) .
\end{aligned}
$$

In matrix notation,

$$
\begin{aligned}
\left(u_{0}, v_{0}\right)+(\delta, 0) & \mapsto\left(x_{0}, y_{0}\right)+(\delta, 0) J \\
\left(u_{0}, v_{0}\right)+(0, \epsilon) & \mapsto\left(x_{0}, y_{0}\right)+(0, \epsilon) J \\
\left(u_{0}, v_{0}\right)+(\delta, \epsilon) & \mapsto\left(x_{0}, y_{0}\right)+(\delta, \epsilon) J+\text { smaller order terms. }
\end{aligned}
$$

where

$$
J=\left(\begin{array}{cc}
v_{0} & -v_{0} \\
u_{0} & 1-u_{0}
\end{array}\right)
$$

You might recognize $J$ as the Jacobian matrix of partial derivatives

$$
\left(\begin{array}{ll}
\frac{\partial x}{\partial u} & \frac{\partial y}{\partial u} \\
\frac{\partial x}{\partial v} & \frac{\partial y}{\partial v}
\end{array}\right)
$$

evaluated at $\left(u_{0}, v_{0}\right)$.
The region $D$ is approximately a parallelogram, with the edges oblique to the coordinate axes. To a good approximation, the area of $D$ is equal to $\delta \epsilon$ times the area of the parallelogram with corners at

$$
(0,0) \quad \text { and } \quad \mathbf{a}=\left(v_{0},-v_{0}\right) \quad \text { and } \quad \mathbf{b}=\left(u_{0}, 1-u_{0}\right) \quad \text { and } \quad \mathbf{a}+\mathbf{b},
$$

which, from the Appendix to this Chapter, equals $|\operatorname{det}(J)|=v_{0}$.
The rest of the calculation of the joint density $\psi$ for $(U, V)$ is easy:

$$
\begin{aligned}
\delta \epsilon \psi\left(u_{0}, v_{0}\right) & \approx \mathbb{P}\{(U, V) \in \Delta\} \\
& =\mathbb{P}\{(X, Y) \in R\} \\
& \approx f\left(x_{0}, y_{0}\right)(\text { area of } D) \approx \frac{x_{0}^{\alpha-1} e^{-x_{0}}}{\Gamma(\alpha)} \frac{y_{0}^{\beta-1} e^{-y_{0}}}{\Gamma(\beta)} \delta \epsilon v_{0}
\end{aligned}
$$

Substitute $x_{0}=u_{0} v_{0}$ and $y_{0}=\left(1-u_{0}\right) v_{0}$ to get the joint density at $\left(u_{0}, v_{0}\right)$ :

$$
\begin{aligned}
\psi\left(u_{0}, v_{0}\right) & =\frac{u_{0}^{\alpha-1} v_{0}^{\alpha-1} e^{-u_{0} v_{0}}}{\Gamma(\alpha)} \frac{\left(1-u_{0}\right)^{\beta-1} v_{0}^{\beta-1} e^{-v_{0}+u_{0} v_{0}}}{\Gamma(\beta)} v_{0} \\
& =\frac{u_{0}^{\alpha-1}\left(1-u_{0}\right)^{\beta-1}}{B(\alpha, \beta)} \times \frac{v_{0}^{\alpha+\beta-1} e^{-v_{0}}}{\Gamma(\alpha+\beta)} \times \frac{\Gamma(\alpha+\beta) B(\alpha, \beta)}{\Gamma(\alpha) \Gamma(\beta)}
\end{aligned}
$$

Once again the final constant must be equal to 1 , which gives the identity

$$
B(\alpha, \beta)=\frac{\Gamma(\alpha) \Gamma(\beta)}{\Gamma(\alpha+\beta)}
$$

The joint density factorizes into a product of the marginal densities: the random variables $U$ and $V$ are independent.

Remark. The fact that $\Gamma(1 / 2)=\sqrt{\pi}$ also follows from the equality

$$
\begin{aligned}
\frac{\Gamma(1 / 2) \Gamma(1 / 2)}{\Gamma(1)}=B(1 / 2,1 / 2) & =\int_{0}^{1} t^{-1 / 2}(1-t)^{-1 / 2} d t \quad \text { put } t=\sin ^{2}(\theta) \\
& =\int_{0}^{\pi / 2} \frac{1}{\sin (\theta) \cos (\theta)} 2 \sin (\theta) \cos (\theta) d \theta=\pi
\end{aligned}
$$

## Example 5

If $X_{1}, X_{2}, \ldots, X_{k}$ are independent random variables, with $X_{i}$ distributed gamma $\left(\alpha_{i}\right)$ for $i=1, \ldots, k$, then

$$
\begin{aligned}
& X_{1}+X_{2} \sim \operatorname{gamma}\left(\alpha_{1}+\alpha_{2}\right) \\
& X_{1}+X_{2}+X_{3}=\left(X_{1}+X_{2}\right)+X_{3} \sim \operatorname{gamma}\left(\alpha_{1}+\alpha_{2}+\alpha_{3}\right) \\
& X_{1}+X_{2}+X_{3}+X_{4}=\left(X_{1}+X_{2}+X_{3}\right)+X_{4} \sim \operatorname{gamma}\left(\alpha_{1}+\alpha_{2}+\alpha_{3}+\alpha_{4}\right) \\
& \cdots \\
& X_{1}+X_{2}+\cdots+X_{k} \sim \operatorname{gamma}\left(\alpha_{1}+\alpha_{2}+\cdots+\alpha_{k}\right)
\end{aligned}
$$

A particular case has great significance for Statistics. Suppose $Z_{1}, \ldots Z_{k}$ are independent random variables, each distributed $\mathrm{N}(0,1)$. From HW6, the random variables $Z_{1}^{2} / 2, \ldots, Z_{k}^{2} / 2$ are independent $\operatorname{gamma}(1 / 2)$ distributed random variables. The sum

$$
\left(Z_{1}^{2}+\cdots+Z_{k}^{2}\right) / 2
$$

must have a gamma $(k / 2)$ distribution with density $t^{k / 2-1} e^{-t} \mathbb{I}\{0<t\} / \Gamma(k / 2)$. It follows that the sum $Z_{1}^{2}+\cdots+Z_{k}^{2}$ has density

$$
\frac{(t / 2)^{k / 2-1} e^{-t / 2} \mathbb{I}\{0<t\}}{2 \Gamma(k / 2)}
$$

This distribution is called the chi-squared on $k$ degrees of freedom, usually denoted by $\chi_{k}^{2}$. The letter $\chi$ is a lowercase Greek chi.

## Appendix: area of a parallelogram

Let $R$ be a parallelogram in the plane with corners at $\mathbf{0}=(0,0)$, and $\mathbf{a}=\left(a_{1}, a_{2}\right)$, and $\mathbf{b}=\left(b_{1}, b_{2}\right)$, and $\mathbf{a}+\mathbf{b}$. The area of $R$ is equal to the absolute value of the determinant of the matrix

$$
J=\left(\begin{array}{ll}
a_{1} & a_{2} \\
b_{1} & b_{2}
\end{array}\right)=\binom{\mathbf{a}}{\mathbf{b}} .
$$

That is, the area of $R$ equals $\left|a_{1} b_{2}-a_{2} b_{1}\right|$.
Proof Let $\theta$ denotes the angle between a and $\mathbf{b}$. Remember that

$$
\|\mathbf{a}\| \times\|\mathbf{b}\| \times \cos (\theta)=\mathbf{a} \cdot \mathbf{b}
$$

With the side from $\mathbf{0}$ to $\mathbf{a}$, which has length $\|\mathbf{a}\|$, as the base, the vertical height is $\|\mathbf{b}\| \times|\sin \theta|$. The absolute value of the area equals $\|\mathbf{a}\| \times\|\mathbf{b}\| \times|\sin \theta|$. The square of the area equals

If you are not sure about the properties of determinants used in the last two lines, you should check directly that

$$
\left(a_{1}^{2}+a_{2}^{2}\right)\left(b_{1}^{2}+b_{2}^{2}\right)-\left(a_{1} b_{1}+a_{2} b_{2}\right)^{2}=\left(a_{1} b_{2}-a_{2} b_{1}\right)^{2}
$$

## Addenda to Chapter 11

I made a horrible mess of the algebra during my discussion in class of Example 11.4. (I plead Monday morning insanity.) Here is the setting: The random variables $X$ and $Y$ have marginal densities

$$
g(x)=x^{\alpha-1} e^{-x} \mathbb{I}\{x>0\} / \Gamma(\alpha) \quad \text { and } \quad h(y)=y^{\beta-1} e^{-y} \mathbb{I}\{y>0\} / \Gamma(\beta)
$$

They have a jointly continuous distribution with joint density

$$
f(x, y)=g(x) h(y)=\frac{x^{\alpha-1} e^{-x} y^{\beta-1} e^{-y}}{\Gamma(\alpha) \Gamma(\beta)} \mathbb{I}\{x>0, y>0\} .
$$

We need to find the joint density function $\psi(u, v)$ for the random variables $U=$ $X /(X+Y)$ and $V=X+Y$.

In class I broke the calculations into two steps:
(i) Define $W=X+Y$. Then $(X, Z)$ has joint density

$$
\begin{aligned}
\psi_{1}(x, w) & =f(x, w-x) \\
& =\frac{x^{\alpha-1} e^{-x}(w-x)^{\beta-1} e^{-w+x}}{\Gamma(\alpha) \Gamma(\beta)} \mathbb{I}\{x>0, w-x>0\} \\
& =\frac{x^{\alpha-1}(w-x)^{\beta-1} e^{-w}}{\Gamma(\alpha) \Gamma(\beta)} \mathbb{I}\{w>x>0\}
\end{aligned}
$$

(ii) Define $V=X / W$. Find the joint densety $\psi_{2}(v, w)$ for $(V, W)$.

Contrary to what I said in class, the region $D$ does not have curvy sides. Even though the transformation $(x, w) \mapsto(v, w)$, where $v=x / w$, is nonlinear, the edges of the region $D$ are all straight. The equation for the left edge is $x=v_{0} w$ for $w_{0} \leq$ $w \leq w_{0}+\epsilon$ and the equation for the right edge is $x=\left(v_{0}+\delta\right) w$ for $w_{0} \leq w \leq w_{0}+\epsilon$. The region $D$ is a quadrilateral but not a parallelogram: the red $\star$ vertex is $\epsilon \delta$ too far to the right to make the left and right edges parallel.

Remark. For general nonlinear maps, the edges of the region $D$ would be curvy. I got a bit carried away with the nonlinearity thing in class.

The area of $D$ is

$$
\frac{1}{2}\left(\delta w_{0}+\delta w_{0}+\delta \epsilon\right) \times \epsilon=\delta \epsilon w_{0}+\frac{1}{2} \delta^{2} \epsilon \approx \delta \epsilon w_{0} .
$$

The final approximation is what you would get if you approximated $D$ by a parallelogram with height $\epsilon$ and base $\delta w_{0}$. The smaller-order term $\delta^{2} \epsilon$ does not matter for the calculation of the joint density.

Now approximate in the usual way to get

$$
\delta \epsilon \psi_{2}\left(v_{0}, w_{0}\right) \approx \mathbb{P}\{(V, W) \in \Delta\}=\mathbb{P}\{(X, W) \in D\} \approx \delta \epsilon w_{0} \psi_{1}\left(x_{0}, w_{0}\right),
$$

which implies

$$
\begin{aligned}
\psi_{2}(v, w)= & w \psi_{1}(v w, w) \\
= & \frac{(v w)^{\alpha-1}(w-v w)^{\beta-1} e^{-w}}{\Gamma(\alpha) \Gamma(\beta)} \mathbb{I}\{w>v w>0\} \\
= & C \times \frac{w^{\alpha+\beta-1} e^{-w} \mathbb{I}\{w>0\}}{\Gamma(\alpha+\beta)} \times \frac{v^{\alpha-1}(1-v)^{\beta-1} \mathbb{I}\{0<v<1\}}{B(\alpha, \beta)} \\
& \quad \text { where } C=\frac{\Gamma(\alpha+\beta) B(\alpha, \beta)}{\Gamma(\alpha) \Gamma(\beta)} .
\end{aligned}
$$

Once again we discover the expression for the beta function from the fact that $C$ must equal 1 (Why?) and also (from the factorization of the joint density) that $V$ has a beta $(\alpha, \beta)$ distribution independently of $W$, which has a gamma $(\alpha+\beta)$ distribution.

And now for something different.

## How to make independent standard normals

Here are the bare bones of the polar coordinates way of manufacturing two independent $N(0,1)$ 's. Start with independent random variables $U \sim \operatorname{Uniform}(0,2 \pi)$ and $W \sim \operatorname{gamma}(1)$ (a.k.a. standard exponential). Define $R=\sqrt{2 W}$ and $X=R \cos (U)$ and $Y=R \sin (U)$. Calculate the density for $R$ as

$$
g(r)=r \exp \left(-r^{2} / 2\right) \mathbb{I}\{r>0\} .
$$

For $0<\theta_{0}<1$ and $r_{0}>0$, and very small $\delta>0$ and $\epsilon>0$, check that the region

$$
D=\left\{(u, r) \in(0,1) \times(0, \infty): \theta_{0} \leq U \leq \theta_{0}+\delta, r_{0} \leq r \leq r_{0}+\epsilon\right\}
$$

corresponds to the region $\Delta$ in the $(X, Y)$-plane that is bounded by circles of radius $r_{0}$ and $r_{0}+\epsilon$ and by radial lines from the origin at angles $\theta_{0}$ and $\theta_{0}+\delta$ to the horizontal axis. The area of $\Delta$ is approximately $2 \pi r_{0} \epsilon \delta$.

Deduce that the joint density $f$ for $(X, Y)$ satisfies

$$
2 \pi r_{0} \epsilon \delta f\left(x_{0}, y_{0}\right) \approx \epsilon g\left(r_{0}\right) \frac{\delta}{2 \pi} \quad \text { where } x_{0}=r_{0} \cos \left(\theta_{0}\right), \quad y_{0}=r_{0} \sin \left(\theta_{0}\right)
$$

That is,

$$
\begin{aligned}
f(x, y) & =\frac{g(r)}{2 \pi r} \quad \text { where } x=r \cos (\theta), \quad y=r \sin (\theta) \\
& =\frac{1}{2 \pi} \exp \left(-\frac{1}{2}\left(x^{2}+y^{2}\right)\right) .
\end{aligned}
$$

## Addenda to Chapter 11

I made a horrible mess of the algebra during my discussion in class of Example 11.4. (I plead Monday morning insanity.) Here is the setting: The random variables $X$ and $Y$ have marginal densities

$$
g(x)=x^{\alpha-1} e^{-x} \mathbb{I}\{x>0\} / \Gamma(\alpha) \quad \text { and } \quad h(y)=y^{\beta-1} e^{-y} \mathbb{I}\{y>0\} / \Gamma(\beta)
$$

They have a jointly continuous distribution with joint density

$$
f(x, y)=g(x) h(y)=\frac{x^{\alpha-1} e^{-x} y^{\beta-1} e^{-y}}{\Gamma(\alpha) \Gamma(\beta)} \mathbb{I}\{x>0, y>0\} .
$$

We need to find the joint density function $\psi(u, v)$ for the random variables $U=$ $X /(X+Y)$ and $V=X+Y$.

In class I broke the calculations into two steps:
(i) Define $W=X+Y$. Then $(X, Z)$ has joint density

$$

The area of $D$ is

$$
\frac{1}{2}\left(\delta w_{0}+\delta w_{0}+\delta \epsilon\right) \times \epsilon=\delta \epsilon w_{0}+\frac{1}{2} \delta^{2} \epsilon \approx \delta \epsilon w_{0} .
$$

The final approximation is what you would get if you approximated $D$ by a parallelogram with height $\epsilon$ and base $\delta w_{0}$. The smaller-order term $\delta^{2} \epsilon$ does not matter for the calculation of the joint density.

Now approximate in the usual way to get

$$
\delta \epsilon \psi_{2}\left(v_{0}, w_{0}\right) \approx \mathbb{P}\{(V, W) \in \Delta\}=\mathbb{P}\{(X, W) \in D\} \approx \delta \epsilon w_{0} \psi_{1}\left(x_{0}, w_{0}\right),
$$

which implies

$$
\begin{aligned}
\psi_{2}(v, w)= & w \psi_{1}(v w, w) \\
= & \frac{(v w)^{\alpha-1}(w-v w)^{\beta-1} e^{-w}}{\Gamma(\alpha) \Gamma(\beta)} \mathbb{I}\{w>v w>0\} \\
= & C \times \frac{w^{\alpha+\beta-1} e^{-w} \mathbb{I}\{w>0\}}{\Gamma(\alpha+\beta)} \times \frac{v^{\alpha-1}(1-v)^{\beta-1} \mathbb{I}\{0<v<1\}}{B(\alpha, \beta)} \\
& \quad \text { where } C=\frac{\Gamma(\alpha+\beta) B(\alpha, \beta)}{\Gamma(\alpha) \Gamma(\beta)} .
\end{aligned}
$$

Once again we discover the expression for the beta function from the fact that $C$ must equal 1 (Why?) and also (from the factorization of the joint density) that $V$ has a beta $(\alpha, \beta)$ distribution independently of $W$, which has a gamma $(\alpha+\beta)$ distribution.

And now for something different.

## How to make independent standard normals

Here are the bare bones of the polar coordinates way of manufacturing two independent $N(0,1)$ 's. Start with independent random variables $U \sim \operatorname{Uniform}(0,2 \pi)$ and $W \sim \operatorname{gamma}(1)$ (a.k.a. standard exponential). Define $R=\sqrt{2 W}$ and $X=R \cos (U)$ and $Y=R \sin (U)$. Calculate the density for $R$ as

$$
g(r)=r \exp \left(-r^{2} / 2\right) \mathbb{I}\{r>0\} .
$$

For $0<\theta_{0}<1$ and $r_{0}>0$, and very small $\delta>0$ and $\epsilon>0$, check that the region

$$
D=\left\{(u, r) \in(0,1) \times(0, \infty): \theta_{0} \leq U \leq \theta_{0}+\delta, r_{0} \leq r \leq r_{0}+\epsilon\right\}
$$

corresponds to the region $\Delta$ in the $(X, Y)$-plane that is bounded by circles of radius $r_{0}$ and $r_{0}+\epsilon$ and by radial lines from the origin at angles $\theta_{0}$ and $\theta_{0}+\delta$ to the horizontal axis. The area of $\Delta$ is approximately $2 \pi r_{0} \epsilon \delta$.

f(x, y) & =\frac{g(r)}{2 \pi r} \quad \text { where } x=r \cos (\theta), \quad y=r \sin (\theta) \\
& =\frac{1}{2 \pi} \exp \left(-\frac{1}{2}\left(x^{2}+y^{2}\right)\right) .
\end{aligned}
$$

## Chapter 12

Conditional densities
Density functions determine continuous distributions. If a continuous distribution is calculated conditionally on some information, then the density is called a conditional density. When the conditioning information involves another random variable with a continuous distribution, the conditional density can be calculated from the joint density for the two random variables.

Suppose $X$ and $Y$ have a jointly continuous distribution with joint density $f(x, y)$. From Chapter 11, you know that the marginal distribution of $X$ has density

$$
g(y)=\int_{-\infty}^{\infty} f(x, y) d x
$$

The conditional distribution for $Y$ given $X=x$ has a (conditional) density, which I will denote by $h(y \mid X=x)$, or just $h(y \mid x)$ if the conditioning variable is unambiguous, for which

$$
\mathbb{P}\{y \leq Y \leq y+\delta \mid X=x\} \approx \delta h(y \mid X=x), \quad \text { for small } \delta>0 .
$$

Conditioning on $X=x$ should be almost the same as conditioning on $x \leq X \leq x+\epsilon$ for a very small $\epsilon>0$. That is, provided $x$ is such that $g(x)>0$,

$$
\begin{aligned}
\mathbb{P}\{y \leq Y \leq y+\delta \mid X=x\} & \approx \mathbb{P}\{y \leq Y \leq y+\delta \mid x \leq X \leq x+\epsilon\} \\
& =\frac{\mathbb{P}\{y \leq Y \leq y+\delta, x \leq X \leq x+\epsilon\}}{\mathbb{P}\{x \leq X \leq x+\epsilon\}} \\
& \approx \frac{\delta \epsilon f(x, y)}{\epsilon g(x)} .
\end{aligned}
$$

In the limit, as $\epsilon$ tends to zero, we are left with $\delta h(y \mid X=x) \approx \delta f(x, y) / g(x)$. That is,

$$
h(y \mid X=x)=f(x, y) / g(x) \quad \text { for each } x \text { with } g(x)>0 .
$$

Symbolically,

Example. Let $X$ and $Y$ be independent random variables, each distributed $N(0,1)$. Define $R=\sqrt{X^{2}+Y^{2}}$. Show that, for each $r>0$, the conditional distribution of $X$ given $R=r$ has density

$$
h(x \mid R=r)=\frac{1}{\pi \sqrt{r^{2}-x^{2}}} \quad \text { for }|x|<r \text { and } r>0 .
$$

The calculation of the conditional density fom Example $<1>$ is easier when expressed in polar coordinates. From Chapter 11, you know that the random variable $R^{2} / 2=\left(X^{2}+Y^{2}\right) / 2$ has a gamma(1) distribution, which is also known as the standard exponential distribution. Building on this connection, in class I showed how to build a pair of independent standard normals $(X, Y)$ their from polar coordinates, starting from a $\Theta \sim \operatorname{Uniform}(0,2 \pi)$ independently of $R=\sqrt{2 W}$, where $W$ has a standard exponential distribution: just put $X=R \cos (\Theta)$ and $Y=R \sin (\Theta)$.

For the question posed in Example $<1>$ we may suppose that $X$ and $Y$ have been constructed from such an $(R, \Theta)$ pair. Thus, for $|x|<r$,

$$
\begin{aligned}
\delta h(x \mid R=r) & \approx \mathbb{P}\{x \leq R \cos (\Theta) \leq x+\delta \mid R=r\} \\
& =\mathbb{P}\{x \leq r \cos (\Theta) \leq x+\delta\} \quad \text { by independence of } R \text { and } \Theta \\
& =\mathbb{P}\left\{\theta_{0}-\epsilon \leq \Theta \leq \theta_{0}\right\}+\mathbb{P}\left\{\theta_{0}-\epsilon+\pi \leq \Theta \leq \theta_{0}+\pi\right\}
\end{aligned}
$$

where $\theta_{0}$ is the unique value in $[0, \pi]$ for which

$$
x / r=\cos \left(\theta_{0}\right) \quad \text { AND } \quad(x+\delta) / r=\cos \left(\theta_{0}-\epsilon\right) \approx \cos \left(\theta_{0}\right)+\epsilon \sin \left(\theta_{0}\right)
$$

Solve (approximately) for $\epsilon$ then substitute into the expression for $\delta h(x \mid R=r)$.

$$
\delta h(x \mid R=r) \approx \frac{2 \epsilon}{2 \pi} \approx \frac{\delta}{\pi r \sin \left(\theta_{0}\right)}=\frac{\delta}{\pi r \sqrt{1-(x / r)^{2}}}, \quad \text { for }|x|<r,
$$

the same as in Example $<1>$.
The final two Examples will demonstrate yet another connection between Poisson processes and order statistics from a uniform distribution. The arguments make use of the obvious generalizations of joint densities and conditional densities to more than two dimensions.

Definition. Say that random variables $X, Y, Z$ have a jointly continuous distribution with joint density $f(x, y, z)$ if

$$
\mathbb{P}\{(X, Y, Z) \in A\}=\iiint \mathbb{I}\{(x, y, z) \in A\} f(x, y, z) d x d y d z \quad \text { for each } A \subseteq \mathbb{R}^{3} .
$$

As in one and two dimensions, joint densities are typically calculated by looking at small regions: for a small region $\Delta$ around $\left(x_{0}, y_{0}, z_{0}\right)$

$$
\mathbb{P}\{(X, Y, Z) \in \Delta\} \approx(\text { volume of } \Delta) \times f\left(x_{0}, y_{0}, z_{0}\right) .
$$

Similarly, the joint density for $(X, Y)$ conditional on $Z=z$ is defined as the function $h(x, y \mid Z=z)$ for which

$$
\mathbb{P}\{(X, Y) \in B \mid Z=z\}=\iiint \mathbb{I}\{(x, y) \in B\} h(x, y \mid Z=z) d x d y
$$

for each subset $B$ of $\mathbb{R}^{2}$. It can be calculated, at $z$ values where the marginal density for $Z$,

$$
g(z)=\iint_{\mathbb{R}^{2}} f(x, y, z) d x d y
$$

is strictly positive, by yet another small-region calculation. If $\Delta$ is a small subset containing ( $x_{0}, y_{0}$ ), then

$$
\begin{aligned}
\mathbb{P}\left\{(X, Y) \in \Delta \mid Z=z_{0}\right\} & \approx \mathbb{P}\left\{(X, Y) \in \Delta \mid z_{0} \leq Z \leq z_{0}+\epsilon\right\} \quad \text { for small } \epsilon>0 \\
& =\frac{\mathbb{P}\left\{(X, Y) \in \Delta, z_{0} \leq Z \leq z_{0}+\epsilon\right\}}{\mathbb{P}\left\{z_{0} \leq Z \leq z_{0}+\epsilon\right\}} \\
& \approx \frac{((\text { area of } \Delta) \times \epsilon) f\left(x_{0}, y_{0}, z_{0}\right)}{\epsilon g\left(z_{0}\right)} \\
& =(\text { area of } \Delta) \frac{f\left(x_{0}, y_{0}, z_{0}\right)}{g\left(z_{0}\right)} .
\end{aligned}
$$

Remark. Notice the identification of $\left\{(x, y, z) \in \mathbb{R}^{3}:(x, y) \in \Delta, z_{0} \leq z \leq z_{0}+\epsilon\right\}$ as a small region with volume equal to (area of $\Delta$ ) $\times \epsilon$.

That is, the conditional (joint) distribution of ( $X, Y$ ) given $Z=z$ has density

$$
h(x, y \mid Z=z)=\frac{f(x, y, z)}{g(z)} \quad \text { provided } g(z)>0 .
$$

Remark. Many authors (me included) like to abbreviate $h(x, y \mid Z=z)$ to $h(x, y \mid z)$. Many others run out of symbols and write $f(x, y \mid z)$ for the conditional (joint) density of ( $X, Y$ ) given $Z=z$. This notation is defensible if one can somehow tell which values are being conditioned on. In a problem with lots of conditioning it can get confusing to remember which $f$ is the joint density and which is conditional on something. To avoid confusion, some authors write things like $f_{X, Y \mid Z}(x, y \mid z)$ for the conditional density and $f_{X}(x)$ for the $X$-marginal density, at the cost of more cumbersome notation.

Example. Let $T_{i}$ denote the time to the $i$ th point in a Poisson process with rate $\lambda$ on $[0, \infty)$. Find the joint distribution of $\left(T_{1}, T_{2}\right)$ conditional on $T_{3}$.

From the result in the previous Example, you should be able to deduce that, conditional on $T_{3}=t_{3}$ for a given $t_{3}>0$, the random variables $\left(T_{1} / T_{3}, T_{2} / T_{3}\right)$ are uniformly distributed over the triangular region $\left\{\left(u_{1} u_{2}\right) \in \mathbb{R}^{2}: 0<u_{1}<u_{2}<1\right\}$. HW11 will step you through an analogous result for order statistics.
$<3>\quad$ Example. Let $U_{(i)}$ for $i=1, \ldots, n$ denote the order statistics for a sample of size $n$ fom the Uniform $(0,1)$ distribution. Find the joint distribution of $\left(U_{(1)}, U_{(2)}\right)$ conditional on $U_{(3)}$.

## Examples for Chapter 12

## Example 1

Let $X$ and $Y$ be independent random variables, each distributed $N(0,1)$. Define $R=$ $\sqrt{X^{2}+Y^{2}}$. For each $r>0$, find the density for the conditional distribution of $X$ given $R=r$.

The joint density for $(X, Y)$ equals

$$
f(x, y)=\frac{1}{2 \pi} \exp \left(-\frac{x^{2}+y^{2}}{2}\right)
$$

To find the joint density for $X$ and $R$, calculate $\mathbb{P}\left\{x_{0} \leq X \leq x_{0}+\delta, r_{0} \leq R \leq r_{0}+\epsilon\right\}$ for small, positive $\delta$ and $\epsilon$. For $\left|x_{0}\right|<r_{0}$, the event corresponds to the two small regions in the $(X, Y)$-plane lying between the lines $x=x_{0}$ and $x=x_{0}+\delta$, and between the circles centered at the origin with radii $r_{0}$ and $r_{0}+\epsilon$.

By symmetry, both regions contribute the same probability. Consider the upper region. For small $\delta$ and $\epsilon$, the region is approximately a parallelogram, with side length $\eta=\sqrt{\left(r_{0}+\epsilon\right)^{2}-x_{0}^{2}}-\sqrt{r_{0}^{2}-x_{0}^{2}}$ and width $\delta$. We could expand the expression for $\eta$ as a power series in $\epsilon$ by multiple applications of Taylor's theorem. It is easier to argue less directly, starting from the equalities

$$
x_{0}^{2}+\left(y_{0}+\eta\right)^{2}=\left(r_{0}+\epsilon\right)^{2} \quad \text { AND } \quad x_{0}^{2}+y_{0}^{2}=r_{0}^{2}
$$

Expand the square on both sides of the first equality, discarding terms ( $\eta^{2}$ and $\epsilon^{2}$ ) of smaller order, to get

$$
x_{0}^{2}+y_{0}^{2}+2 \eta y_{0} \approx r_{0}^{2}+2 r_{0} \epsilon,
$$

then invoke the second equality to deduce that $\eta \approx\left(r_{0} \epsilon / y_{0}\right)$. The upper region has approximate area $r_{0} \epsilon \delta / y_{0}$, which implies

$$
\begin{aligned}
\mathbb{P}\left\{x_{0} \leq X \leq x_{0}+\delta, r_{0} \leq R \leq r_{0}+\epsilon\right\} & =2 \frac{r_{0} \epsilon \delta}{y_{0}} f\left(x_{0}, y_{0}\right)+\text { smaller order terms } \\
& \approx \frac{2 r_{0}}{\sqrt{r_{0}^{2}-x_{0}^{2}}} \frac{\exp \left(-r_{0}^{2} / 2\right)}{2 \pi} \epsilon \delta .
\end{aligned}
$$

The random variables $X$ and $R$ have joint density

$$
\psi(x, r)=\frac{r \exp \left(-r^{2} / 2\right)}{\pi \sqrt{r^{2}-x^{2}}} \quad \text { for }|x| \leq r \text { and } r>0
$$

Once again I have omitted the subscript on the dummy variables, to indicate that the argument works for every $x, r$ in the specified range.

The random variable $R$ has marginal density

$$
\begin{aligned}
g(r)=\int_{-r}^{r} \psi(x, r) d x & =\frac{r \exp \left(-r^{2} / 2\right)}{\pi} \int_{-r}^{r} \frac{d x}{\sqrt{r^{2}-x^{2}}} \quad \text { put } x=r \cos \theta \\
& =\frac{r \exp \left(-r^{2} / 2\right)}{\pi} \int_{\pi}^{0} \frac{-r \sin \theta}{r \sin \theta} d \theta=r \exp \left(-r^{2} / 2\right) \quad \text { for } r>0 .
\end{aligned}
$$

The conditional density for $X$ given $R=r$ equals

$$
h(x \mid R=r)=\frac{\psi(x, r)}{g(r)}=\frac{1}{\pi \sqrt{r^{2}-x^{2}}} \quad \text { for }|x|<r \text { and } r>0 .
$$

## Example 2

Let $T_{i}$ denote the time to the $i$ th point in a Poisson process with rate $\lambda$ on $[0, \infty)$. Find the joint distribution of $\left(T_{1}, T_{2}\right)$ conditional on $T_{3}$.

For fixed $0<t_{1}<t_{2}<t_{3}<\infty$ and suitably small positive $\delta_{1}, \delta_{2}, \delta_{3}$ define disjoint intervals

$$
\begin{aligned}
& I_{1}=\left[0, t_{1}\right) \quad I_{2}=\left[t_{1}, t_{1}+\delta_{1}\right] \quad I_{3}=\left(t_{1}+\delta_{1}, t_{2}\right), \\
& I_{4}=\left[t_{2}, t_{2}+\delta_{2}\right], \quad I_{5}=\left(t_{2}+\delta_{2}, t_{3}\right), \quad I_{6}=\left[t_{3}, t_{3}+\delta_{3}\right] .
\end{aligned}
$$

Write $N_{j}$ for the number of points landing in $I_{j}$. The random variables $N_{1}, \ldots, N_{6}$ are independent Poissons, with expected values

$$
\lambda t_{1}, \quad \lambda \delta_{1}, \quad \lambda\left(t_{2}-t_{1}-\delta_{1}\right), \quad \lambda \delta_{2}, \quad \lambda\left(t_{3}-t_{2}-\delta_{2}\right), \quad \lambda \delta_{3} .
$$

To calculate the joint density for $\left(T_{1}, T_{2}, T_{3}\right)$ start from

$$
\begin{aligned}
& \mathbb{P}\left\{t_{1} \leq T_{1} \leq t_{1}+\delta_{1}, t_{2} \leq T_{2} \leq t_{2}+\delta_{2}, t_{3} \leq T_{3} \leq t_{3}+\delta_{3}\right\} \\
& \quad=\mathbb{P}\left\{N_{1}=0, N_{2}=1, N_{3}=0, N_{4}=1, N_{5}=0, N_{6}=1\right\} \\
& \quad+\text { smaller order terms. }
\end{aligned}
$$

Here the "smaller order terms" involve probabilities of subsets of events such as $\left\{N_{2} \geq 2, N_{4} \geq 1, N_{6} \geq 1\right\}$, which has probability equal to

$$
\mathbb{P}\left\{N_{2} \geq 2\right\} \mathbb{P}\left\{N_{4} \geq 1\right\} \mathbb{P}\left\{N_{6} \geq 1\right\}=O\left(\delta_{1}^{2}\right) O\left(\delta_{2}\right) O\left(\delta_{3}\right)
$$

Remark. The "big-oh" notation indicates terms that are bounded by constant multiples of the arguments. For example, the $O\left(\delta_{1}^{2}\right)$ term, which is bounded by a constant multiple of $\delta_{1}^{2}$, accounts for various events involving $N_{2} \geq 2$.

Independence also gives a factorization of the main contribution:

$$
\begin{aligned}
& \mathbb{P}\left\{N_{1}=0, N_{2}=1, N_{3}=0, N_{4}=1, N_{5}=0, N_{6}=1\right\} \\
& \quad=\mathbb{P}\left\{N_{1}=0\right\} \mathbb{P}\left\{N_{2}=1\right\} \mathbb{P}\left\{N_{3}=0\right\} \mathbb{P}\left\{N_{4}=1\right\} \mathbb{P}\left\{N_{5}=0\right\} \mathbb{P}\left\{N_{6}=1\right\} \\
& \quad=\left(e^{-\lambda t_{1}}\right)\left[\lambda \delta_{1}+O\left(\delta_{1}^{2}\right)\right]\left(e^{-\lambda\left(t_{2}-t_{1}-\delta_{1}\right)}\right)\left[\lambda \delta_{2}+O\left(\delta_{2}^{2}\right)\right]\left(e^{-\lambda\left(t_{3}-t_{2}-\delta_{2}\right)}\right)\left[\lambda \delta_{3}+O\left(\delta_{3}^{2}\right)\right] .
\end{aligned}
$$

Here I have used the expansion $\mathbb{P}\{X=1\}=\mu e^{-\mu}=\mu+O\left(\mu^{2}\right)$ if $X \sim \operatorname{Poisson}(\mu)$ with $\mu$ near 0 . While I am at it, I should also replace $e^{\lambda \delta_{j}}$ by $1+O\left(\delta_{j}\right)$, for $j=1,2$. The point of this notation is to simplify the expansion of all the products, leaving

$$
\lambda^{3} \delta_{1} \delta_{2} \delta_{3} e^{-\lambda t_{3}}+O\left(\delta_{1}^{2} \delta_{2} \delta_{3}\right)+O\left(\delta_{1} \delta_{2}^{2} \delta_{3}\right)+O\left(\delta_{1} \delta_{2} \delta_{3}^{2}\right)
$$

If you think of $\Delta$ as a small shoebox (hyperrectangle) with sides $\delta_{1}, \delta_{2}$, and $\delta_{3}$, with all three $\delta_{j}$ 's of comparable magnitude (you could even take $\delta_{1}=\delta_{2}=\delta_{3}$ ), the preceding calculations reduce to

$$
\mathbb{P}\left\{\left(T_{1}, T_{2}, T_{3}\right) \in \Delta\right\}=(\text { volume of } \Delta) \lambda^{3} e^{-\lambda t_{3}}+\text { smaller order terms }
$$

where the "smaller order terms" are small relative to the volume of $\Delta$. Thus the joint density for $\left(T_{1}, T_{2}, T_{3}\right)$ is

$$
f\left(t_{1}, t_{2}, t_{3}\right)=\lambda^{3} e^{-\lambda t_{3}} \mathbb{I}\left\{0<t_{1}<t_{2}<t_{3}\right\} .
$$

Remark. The indicator function is very important. Without it you would be unpleasantly surprised to find $\iiint_{\mathbb{R}^{3}} f=\infty$.

Just as a check, calculate the marginal density for $T_{3}$ as

$$
\begin{aligned}
g\left(t_{3}\right) & =\iint_{\mathbb{R}^{2}} f\left(t_{1}, t_{2}, t_{3}\right) d t_{1} d t_{2} \\
& =\lambda^{3} e^{-\lambda t_{3}} \iint \mathbb{I}\left\{0<t_{1}<t_{2}<t_{3}\right\} d t_{1} d t_{2} .
\end{aligned}
$$

The double integral equals

$$
\int \mathbb{I}\left\{0<t_{2}<t_{3}\right\}\left(\int_{0}^{t_{2}} 1 d t_{1}\right)=\int_{0}^{t_{3}} t_{2} d t_{2}=\frac{1}{2} t_{3}^{2} .
$$

That is, $T_{3}$ has marginal density

$$
g\left(t_{3}\right)=\frac{1}{2} \lambda^{3} t_{3}^{2} e^{-\lambda t_{3}} \mathbb{I}\left\{t_{3}>0\right\},
$$

which agrees with the result calculated in Example 10.1.
Now, arguing as for $(\star)$, calculate the conditional density for a given $t_{3}>0$ as

$$
\begin{aligned}
h\left(t_{1}, t_{2} \mid T_{3}=t_{3}\right) & =\frac{f\left(t_{1}, t_{2}, t_{3}\right)}{g\left(t_{3}\right)} \\
& =\frac{\lambda^{3} e^{-\lambda t_{3}} \mathbb{I}\left\{0<t_{1}<t_{2}<t_{3}\right\}}{\frac{1}{2} \lambda^{3} t_{3}^{2} e^{-\lambda t_{3}}} \\
& =\frac{2}{t_{3}^{2}} \mathbb{I}\left\{0<t_{1}<t_{2}<t_{3}\right\} .
\end{aligned}
$$

That is, conditional on $T_{3}=t_{3}$, the pair $\left(T_{1}, T_{2}\right)$ is uniformly distributed in a triangular region of area $t_{3}^{2} / 2$.

## Chapter 13

## Multivariate normal distributions

The multivariate normal is the most useful, and most studied, of the standard joint distributions. A huge body of statistical theory depends on the properties of families of random variables whose joint distributions are at least approximately multivariate normal. The bivariate case (two variables) is the easiest to understand, because it requires a minimum of notation. Vector notation and matrix algebra becomes necessities when many random variables are involved: for random variables $X_{1}, \ldots, X_{n}$ write $\mathbf{X}$ for the random vector $\left(X_{1}, \ldots, X_{n}\right)$, and $\mathbf{x}$ for the generic point $\left(x_{1}, \ldots, x_{n}\right)$ in $\mathbb{R}^{n}$.

Remark. In general, if $W=\left(W_{i j}\right)$ is an $m \times n$ matrix whose elements are random variables, the $m \times n$ matrix $\mathbb{E} W$ is defined to have $(i, j)$ th element $\mathbb{E} W_{i j}$. That is, expectations are taken element-wise. If $B$ is an $n \times p$ matrix of constants then $W B$ has $(i, j)$ th element $\sum_{k=1}^{n} W_{i k} B_{k j}$ whose expected value equals $\sum_{k=1}^{n}\left(\mathbb{E} W_{i k}\right) B_{\ell j}$, the $(i, j)$ th element of the matrix $(\mathbb{E} W) B$. That is, $\mathbb{E}(W B)=(\mathbb{E} W) B$. Similarly, for an $\ell \times m$ matrix of constants $A$, the expected value of $A W$ equals $A(\mathbb{E} W)$.

For a $1 \times n$ vector of random variables $\mathbf{X}=\left(X_{1}, \ldots, X_{n}\right)$, with expected value $\mu=\mathbb{E} X$, the variance matrix $\operatorname{var}(X)$ is defined to be the $n \times n$ matrix $\mathbb{E}(\mathbf{X}-\boldsymbol{\mu})^{\prime}(\mathbf{X}-\boldsymbol{\mu})$, whose $(i, j)$ th element equals $\mathbb{E}\left(X_{i}-\mu_{i}\right)\left(X_{j}-\mu_{j}\right)=$ $\operatorname{cov}\left(X_{i}, X_{j}\right)$.

For random vectors $\mathbf{x}$ and $\mathbf{Y}$ with expected values $\boldsymbol{\mu}_{X}$ and $\mu_{Y}$, the covariance matrix equals $\mathbb{E}\left(\mathbf{X}-\boldsymbol{\mu}_{X}\right)^{\prime}\left(\mathbf{Y}-\boldsymbol{\mu}_{Y}\right)$, whose $(i, j)$ th elements equals $\operatorname{cov}\left(X_{i}, Y_{j}\right)$.

As an exercise you should check that, for an $n \times p$ matrix $B$ of constants, $\operatorname{var}(\mathbf{X} B)=B^{\prime} \operatorname{var}(\mathbf{X}) B$. Other results for variance (and covariance matrices) can be derived similarly.

Be careful when checking these definitions against Wikipedia. I have made my random vectors row vectors; some authors use column vectors.

Definition. Random variables $X_{1}, X_{2}, \ldots, X_{n}$ are said to have a jointly continuous distribution with joint density function $f\left(x_{1}, x_{2}, \ldots, x_{n}\right)$ if, for each subset $A$ of $\mathbb{R}^{n}$,

$$
\begin{aligned}
\mathbb{P}\{\mathbf{X} \in A\} & =\iint \ldots \int\left\{\left(x_{1}, x_{2}, \ldots x_{n}\right) \in A\right\} f\left(x_{1}, x_{2}, \ldots, x_{n}\right) d x_{1} d x_{2} \ldots d x_{n} \\
& =\int\{\mathbf{x} \in A\} f(\mathbf{x}) d \mathbf{x},
\end{aligned}
$$

where $\int \ldots d \mathbf{x}$ is an abbreviation for the $n$-fold integral.

For small regions $\Delta$ containing a point $\mathbf{x}$,

$$
\frac{\mathbb{P}\{\mathbf{X} \in \Delta\}}{\operatorname{vol}(\Delta)} \rightarrow f(\mathbf{x}) \quad \text { as } \Delta \text { shrinks down to } \mathbf{x} .
$$

Here $\operatorname{vol}(\Delta)$ denotes the $n$-dimensional volume of $\Delta$.
The density $f$ must be nonnegative and integrate to one over $\mathbb{R}^{n}$. If the random variables $X_{1}, \ldots, X_{n}$ are independent, the joint density function is equal to the product of the marginal densities for each $X_{i}$, and conversely. The proof is similar to the proof for the bivariate case. For example, if $Z_{1}, \ldots, Z_{n}$ are independent and each $Z_{i}$ has a $N(0,1)$ distribution, the joint density is

$$
\begin{aligned}
f\left(z_{1}, \ldots, z_{n}\right) & =(2 \pi)^{-n / 2} \exp \left(-\sum_{i \leq n} z_{i}^{2} / 2\right) \quad \text { for all } z_{1}, \ldots, z_{n} \\
& =(2 \pi)^{-n / 2} \exp \left(-\|\mathbf{z}\|^{2} / 2\right) \quad \text { for all } \mathbf{z} .
\end{aligned}
$$

This joint distribution is denoted by $N\left(\mathbf{0}, I_{n}\right)$. It is often referred to as the spherical normal distribution, because of the spherical symmetry of the density. The $N\left(\mathbf{0}, I_{n}\right)$ notation refers to the vector of means and the variance matrix,

$$
\mathbb{E} \mathbf{Z}=\left(\mathbb{E} Z_{1}, \ldots, \mathbb{E} Z_{n}\right)=\mathbf{0} \quad \text { AND } \quad \operatorname{var}(\mathbf{Z})=I_{n}
$$

Remark. More generally, if $X=\mu+\mathbf{Z} A$, where $\mu$ is a constant vector in $\mathbb{R}^{n}$ and $A$ is a matrix of constants and $\mathbf{Z}=N\left(\mathbf{0}, I_{n}\right)$, then

$$
\mathbb{E} \mathbf{X}=\mu \quad \text { AND } \quad \operatorname{var}(\mathbf{X})=V=A^{\prime} A .
$$

If the variance matrix $V$ is non-singular, the $n$-dimensional analog of the methods in Chapter 11 show that $\mathbf{X}$ has joint density

$$
f(\mathbf{x})=(2 \pi)^{-n / 2}|\operatorname{det}(V)|^{-1 / 2} \exp \left(-\frac{1}{2}(\mathbf{x}-\boldsymbol{\mu}) V^{-1}(\mathbf{x}-\boldsymbol{\mu})^{\prime}\right)
$$

This distribution is denoted by $N(\boldsymbol{\mu}, V)$.
You don't really need to know about the general $N(\boldsymbol{\mu}, V)$ density for this course.

The distance of the random vector $\mathbf{Z}$ from the origin is $\|\mathbf{Z}\|=\sqrt{Z_{1}^{2}+\cdots+Z_{n}^{2}}$. From Chapter 11, if $\mathbf{Z} \sim N\left(\mathbf{0}, I_{n}\right)$ you know that $\|\mathbf{Z}\|^{2} / 2$ has a gamma $(n / 2)$ distribution. The distribution of $\|\mathbf{Z}\|^{2}$ is given another special name, because of its great importance in the theory of statistics.

Definition. Let $\mathbf{Z}=\left(Z_{1}, Z_{2}, \ldots, Z_{n}\right)$ have a spherical normal distribution, $N\left(\mathbf{0}, I_{n}\right)$. The chi-square, $\chi_{n}^{2}$, is defined as the distribution of $\|\mathrm{Z}\|^{2}=Z_{1}^{2}+\cdots+Z_{n}^{2}$.

The methods for finding (bivariate) joint densities for functions of two random variables with jointly continuous distributions extend to multivariate distributions. Admittedly there is a problem with the drawing of pictures in $n$ dimensions, to keep track of the transformations, and one must remember to say " $n$-dimensional volume" instead of area, but otherwise calculations are not much more complicated than in two dimensions.

The spherical symmetry of the $N\left(\mathbf{0}, I_{n}\right)$ makes some arguments particularly easy. Let me start with the two-dimensional case. Suppose $Z_{1}$ and $Z_{2}$ have independent $N(0,1)$ distributions, defining a random point $\mathbf{Z}=\left(Z_{1}, Z_{2}\right)$ in the plane. You could also write $\mathbf{Z}$ as $Z_{1} \mathbf{e}_{1}+Z_{2} \mathbf{e}_{2}$, where $\mathbf{e}_{1}=(1,0)$ and $\mathbf{e}_{2}=(0,1)$. Rotate the coordinate axes through an angle $\alpha$, writing $\mathbf{W}=\left(W_{1}, W_{2}\right)$ for the coordinates of the random point in the new coordinate system.

The new axes are defined by the unit vectors

$$
\mathbf{q}_{1}=(\cos \alpha, \sin \alpha) \quad \text { AND } \quad \mathbf{q}_{2}=(-\sin \alpha, \cos \alpha) .
$$

Remark. Note that $\mathbf{q}_{1}$ and $\mathbf{q}_{2}$ are orthogonal because $\mathbf{q}_{1} \cdot \mathbf{q}_{2}=0$.
The representation $\mathbf{Z}=\left(Z_{1}, Z_{2}\right)=W_{1} \mathbf{q}_{1}+W_{2} \mathbf{q}_{2}$ gives

$$
\begin{aligned}
& W_{1}=\mathbf{Z} \cdot \mathbf{q}_{1}=Z_{1} \cos \alpha+Z_{2} \sin \alpha \\
& W_{2}=\mathbf{Z} \cdot \mathbf{q}_{2}=-Z_{1} \sin \alpha+Z_{2} \cos \alpha .
\end{aligned}
$$

That is, $W_{1}$ and $W_{2}$ are both linear functions of $Z_{1}$ and $Z_{2}$. The random variables $\mathbf{W}=\left(W_{1}, W_{2}\right)$ have a multivariate normal distribution with $\mathbb{E} \mathbf{W}=\mathbf{0}$ and

$$
\begin{aligned}
\operatorname{var}\left(W_{1}\right) & =\cos ^{2} \alpha+\sin ^{2} \alpha=1 \\
\operatorname{var}\left(W_{2}\right) & =\sin ^{2} \alpha+\cos ^{2} \alpha=1 \\
\operatorname{cov}\left(W_{1}, W_{2}\right) & =(\cos \alpha)(-\sin \alpha)+(\sin \alpha)(\cos \alpha)=0 .
\end{aligned}
$$

More succinctly, $\operatorname{var}(\mathbf{W})=I_{2}$, a property that you could check more cleanly using the representation $\mathbf{W}=\mathbf{Z} Q^{\prime}$, where $Q$ is the orthogonal matrix with rows $\mathbf{q}_{1}$ and $\mathbf{q}_{2}$. In fact, the random variables $W_{1}$ and $W_{2}$ are independent and each is distributed $N(0,1)$. I won't give all the details for the two-dimensional case because the argument in higher dimensions also works for $\mathbb{R}^{2}$.
$<1>\quad$ Example. Suppose $\mathbf{Z} \sim N\left(\mathbf{0}, I_{n}\right)$. Let $\mathbf{q}_{1}, \ldots, \mathbf{q}_{n}$ be a new orthonormal basis for $\mathbb{R}^{n}$, and let $\mathbf{Z}=W_{1} \mathbf{q}_{1}+\cdots+W_{n} \mathbf{q}_{n}$ be the representation for $\mathbf{Z}$ in the new basis. Then the $W_{1}, \ldots, W_{n}$ are also independent $N(0,1)$ distributed random variables.

To prove results involving the spherical normal it is often merely a matter of transforming to an appropriate orthonormal basis. This technique greatly simplifies the study of statistical problems based on multivariate normal models.
$<2>\quad$ Example. Suppose $Z_{1}, Z_{2}, \ldots, Z_{n}$ are independent, each distributed $N(0,1)$. Define $\bar{Z}=\left(Z_{1}+\cdots+Z_{n}\right) / n$ and $T=\sum_{i \leq n}\left(Z_{i}-\bar{Z}\right)^{2}$. Show that $\bar{Z}$ has a $N(0,1 / n)$ distribution independently of $T$, which has a $\chi_{n-1}^{2}$ distribution.

Statistical problems often deal with independent random variables $Y_{1}, \ldots, Y_{n}$ each distributed $N\left(\mu, \sigma^{2}\right)$, where $\mu$ and $\sigma^{2}$ are unknown parameters that need to be estimated. If we define $Z_{i}=\left(Y_{i}-\mu\right) / \sigma$ then the $Z_{i}$ are as in the previous Example. Moreover,

$$
\begin{aligned}
\bar{Y}=\frac{1}{n} \sum_{i \leq n} Y_{i} & =\mu+\sigma \bar{Z} \sim N\left(\mu, \sigma^{2} / n\right) \\
\sum_{i \leq n}\left(Y_{i}-\bar{Y}\right)^{2} / \sigma^{2} & =\sum_{i \leq n}\left(Z_{i}-\bar{Z}\right)^{2} \sim \chi_{n-1}^{2},
\end{aligned}
$$

from which it follows that $\bar{Y}$ and $\widehat{\sigma}^{2}:=\sum_{i \leq n}\left(Y_{i}-\bar{Y}\right)^{2} /(n-1)$ are independent.
Remark. It is traditional to use $\bar{Y}$ to estimate $\mu$ and $\hat{\sigma}^{2}$ to estimate $\sigma^{2}$. The random variable $\sqrt{n}(\bar{Y}-\mu) / \widehat{\sigma}$ has the same distribution as $U / \sqrt{V /(n-1)}$, where $U \sim N(0,1)$ independently of $V \sim \chi_{n-1}^{2}$. By definition, such a ratio is said to have a $t$ distribution on $n-1$ degrees of freedom.

Example. Distribution of least squares estimators for regression.

## Examples for Chapter 13

## Example 1

We have $\mathbf{Z} \sim N\left(\mathbf{0}, I_{n}\right)$ and $\mathbf{q}_{1}, \ldots, \mathbf{q}_{n}$ a new orthonormal basis for $\mathbb{R}^{n}$. In the new coordinate system, $\mathbf{Z}=W_{1} \mathbf{q}_{1}+\cdots+W_{n} \mathbf{q}_{n}$ We need to show that the $W_{1}, \ldots, W_{n}$ are also independent $N(0,1)$ distributed random variables.

The picture shows only two of the $n$ coordinates; the other $n-2$ coordinates are sticking out of the page. I have placed the pictures for the $\mathbf{w}$ - and $\mathbf{z}$-spaces on top of each other, so that you can see how the balls $B$ and $B^{*}$ line up.

For a small ball $B$ centered at $\mathbf{z}$,

$$
\mathbb{P}\{\mathbf{Z} \in B\} \approx f(\mathbf{z})(\text { volume of } B) \quad \text { where } f(\mathbf{z})=(2 \pi)^{-n / 2} \exp \left(-\|\mathbf{z}\|^{2} / 2\right)
$$

The corresponding region for $\mathbf{W}$ is $B^{*}$, a ball of the same radius, but centered at the point $\mathbf{w}=\left(w_{1}, \ldots, w_{n}\right)$ for which $w_{1} \mathbf{q}_{1}+\cdots+w_{n} \mathbf{q}_{n}=\mathbf{z}$. Thus

$$
\mathbb{P}\left\{\mathbf{W} \in B^{*}\right\}=\mathbb{P}\{\mathbf{Z} \in B\} \approx(2 \pi)^{-n / 2} \exp \left(-\frac{1}{2}\|\mathbf{x}\|^{2}\right)(\text { volume of } B)
$$

From the equalities

$$
\|\mathbf{w}\|=\|\mathbf{z}\| \quad \text { AND } \quad \text { volume of } B=\text { volume of } B^{*},
$$

we get

$$
\mathbb{P}\left\{\mathbf{W} \in B^{*}\right\} \approx(2 \pi)^{-n / 2} \exp \left(-\frac{1}{2}\|\mathbf{w}\|^{2}\right)\left(\text { volume of } B^{*}\right)
$$

That is, $\mathbf{W}$ has the asserted $N\left(\mathbf{0}, I_{n}\right)$ density.

## Example 2

Suppose $Z_{1}, Z_{2}, \ldots, Z_{n}$ are independent, each distributed $N(0,1)$. Define

$$
\bar{Z}=\frac{Z_{1}+\cdots+Z_{n}}{n} \quad \text { and } \quad T=\sum_{i \leq n}\left(Z_{i}-\bar{Z}\right)^{2}
$$

Show that $\bar{Z}$ has a $N(0,1 / n)$ distribution independently of $T$, which has a $\chi_{n-1}^{2}$ distribution.
Choose the new orthonormal basis with $\mathbf{q}_{1}=(1,1, \ldots, 1) / \sqrt{n}$. Choose $\mathbf{q}_{2}, \ldots, \mathbf{q}_{n}$ however you like, provided they are orthogonal unit vectors, all orthogonal to $\mathbf{q}_{1}$. In the new coordinate system,

$$
\mathbf{Z}=W_{1} \mathbf{q}_{1}+\cdots+W_{n} \mathbf{q}_{n} \quad \text { where } W_{i}=\mathbf{Z} \cdot \mathbf{q}_{i} \text { for each } i
$$

In particular,

$$
W_{1}=\mathbf{Z} \cdot \mathbf{q}_{1}=\frac{Z_{1}+\cdots+Z_{n}}{\sqrt{n}}=\sqrt{n} \bar{Z}
$$

From Example $<1>$ you know that $W_{1}$ has a $N(0,1)$ distribution. It follows that $\bar{Z}$ has a $N(0,1 / n)$ distribution.

The random variable $T$ equals the squared length of the vector

$$
\left(Z_{1}-\bar{Z}, \ldots, Z_{n}-\bar{Z}\right)=\mathbf{Z}-\bar{Z}\left(\sqrt{n} \mathbf{q}_{1}\right)=\mathbf{Z}-W_{1} \mathbf{q}_{1}=W_{2} \mathbf{q}_{2}+\cdots+W_{n} \mathbf{q}_{n}
$$

That is,

$$
T=\left\|W_{2} \mathbf{q}_{2}+\cdots+W_{n} \mathbf{q}_{n}\right\|^{2}=W_{2}^{2}+\cdots+W_{n}^{2}
$$

a sum of squares of $n-1$ independent $N(0,1)$ random variables, which has a $\chi_{n-1^{-}}^{2}$ distribution.

Finally, notice that $\bar{Z}$ is a function of $W_{1}$, whereas $T$ is a function of the independent random variables $W_{2}, \ldots, W_{n}$. The independence of $\bar{Z}$ and $T$ follows.

## Example 3

Suppose $Y_{1}, \ldots Y_{n}$ are independent random variables, with $Y_{i} \sim N\left(\mu_{i}, \sigma^{2}\right)$ for an unknown $\sigma^{2}$. Suppose also that $\mu_{i}=\alpha+\beta x_{i}$, for unknown parameters $\alpha$ and $\beta$ and observed constants $x_{1}, \ldots, x_{n}$ with average $\bar{x}=\sum_{i \leq n} x_{i} / n$.

The method of least squares estimates the parameters $\alpha$ and $\beta$ by the values $\widehat{a}$ and $\widehat{b}$ that minimize

$$
S^{2}(a, b)=\sum_{i \leq n}\left(Y_{i}-a-b x_{i}\right)^{2}
$$

over all $(a, b)$ in $\mathbb{R}^{2}$. One then estimates $\sigma^{2}$ by the value $\widehat{\sigma}^{2}=S^{2}(\widehat{a}, \widehat{b}) /(n-2)$.
In what follows I will assume that $T:=\sum_{i=1}^{n}\left(x_{i}-\bar{x}\right)^{2}>0$. (If $T$ were zero then all the $x_{i}$ would be equal, which would make $\mathbf{x}=\bar{x} 1$.)

Define $\mathbf{Y}=\left(Y_{1}, \ldots, Y_{n}\right)$ and $\mathbf{x}=\left(x_{1}, \ldots, x_{n}\right)$ and $\mathbf{1}=(1,1, \ldots, 1)$. Then

$$
\mathbb{E} \mathbf{Y}=\boldsymbol{\mu}=\alpha \mathbf{1}+\beta \mathbf{x} \quad \text { AND } \quad \mathbf{Y}=\boldsymbol{\mu}+\sigma \mathbf{Z} \quad \text { where } \mathbf{Z} \sim N\left(\mathbf{0}, I_{n}\right)
$$

and

$$
S^{2}(a, b)=\|\mathbf{Y}-a \mathbf{1}-b \mathbf{x}\|^{2} .
$$

Create a new orthonormal basis for $\mathbb{R}^{n}$ by taking

$$
\mathbf{q}_{1}=(1,1, \ldots, 1) / \sqrt{n} \quad \text { AND } \quad \mathbf{q}_{2}=\frac{\mathbf{x}-\bar{x} \mathbf{1}}{\|\mathbf{x}-\bar{x} \mathbf{1}\|}
$$

Choose $\mathbf{q}_{3}, \ldots, \mathbf{q}_{n}$ however you like, provided they are orthogonal unit vectors, all orthogonal to $\mathbf{q}_{1}$.

Remark. You should check that $\mathbf{q}_{1} \cdot \mathbf{q}_{2}=0$ and $\left\|\mathbf{q}_{1}\right\|=\left\|\mathbf{q}_{2}\right\|=1$. Also note that $\|\mathrm{x}-\bar{x} 1\|=\sqrt{T}$.

The vectors $\mathbf{1}, \mathbf{x}$ and $\mathbf{q}_{1}, \mathbf{q}_{2}$ span the same two-dimensional subspace of $\mathbb{R}^{2}$. That is, any vector that can be written as a linear combination of $\mathbf{1}$ and $\mathbf{x}$ can also be written as a linear combination of $\mathbf{q}_{1}$ and $\mathbf{q}_{2}$; and any vector that can be written as a linear combination of $\mathbf{q}_{1}$ and $\mathbf{q}_{2}$ can also be written as a linear combination of $\mathbf{1}$ and $\mathbf{x}$. Put another way, for each pair $a, b$ there is a unique pair $c, d$ for which $a \mathbf{1}+b \mathbf{x}=c \mathbf{q}_{1}+d \mathbf{q}_{2}$.

Remark. In matrix form, $(a, b) X=(c, d) Q$, where $X$ is the $2 \times 2$ matrix with rows $\mathbf{1}$ and $\mathbf{x}$, and $Q$ is the $2 \times 2$ orthogonal matrix with rows $\mathbf{q}_{1}$ and $\mathbf{q}_{2}$. The two matrices are related by $X=R Q$ and $Q=R^{-1} X$ where

$$
R=\left(\begin{array}{cc}
\sqrt{n} & 0 \\
\sqrt{n} \bar{x} & \sqrt{T}
\end{array}\right) \quad \text { AND } \quad R^{-1}=\left(\begin{array}{cc}
1 / \sqrt{n} & 0 \\
-\bar{x} / \sqrt{T} & 1 / \sqrt{T}
\end{array}\right) .
$$

Thus $(a, b) X=(c, d) Q$ if and only if $(a, b) R=(c, d)$ if and only if $(a, b)=$ $(c, d) R^{-1}$. That is,

$$
\begin{array}{rll}
c=\sqrt{n}(a+b \bar{x}), & d=\sqrt{T} b \\
a=c / \sqrt{n}-d \bar{x} / \sqrt{T}, & b=d / \sqrt{T} .
\end{array}
$$

The calculations for transforming between coordinate systems are easier if you work with matrix notation.

## The least squares problem

Write all the vectors in the new basis:

$$
\begin{aligned}
\widehat{a} \mathbf{1}+\widehat{b} \mathbf{x} & =(\widehat{a}+\widehat{b} \bar{x}) \mathbf{1}+\widehat{b}(\mathbf{x}-\bar{x} \mathbf{1}) \\
& =\widehat{c} \mathbf{q}_{1}+\widehat{d} \mathbf{q}_{2} \quad \text { where } \widehat{c}=(\widehat{a}+\widehat{b} \bar{x}) \sqrt{n} \text { and } \widehat{d}=\widehat{b} \sqrt{T},
\end{aligned}
$$

and

$$
\mathbf{Y}=\sum_{i \leq n} g_{i} \mathbf{q}_{i} \quad \text { where } g_{i}:=\mathbf{Y} \cdot \mathbf{q}_{i}
$$

Remark. By direct calculation, $g_{1}=\mathbf{Y} \cdot \mathbf{1} / \sqrt{n}=\bar{Y} \sqrt{n}$, where $\bar{Y}=\sum_{i \leq n} Y_{i} / n$,

$$
\text { and } g_{2}=\mathbf{Y} \cdot(\mathbf{x}-\bar{x} \mathbf{1}) / \sqrt{T}=\sum_{i \leq n} Y_{i}\left(x_{i}-\bar{x}\right) / \sqrt{\sum_{i \leq n}\left(x_{i}-\bar{x}\right)^{2}} .
$$

The quantities $\widehat{c}$ and $\widehat{d}$ minimize, over all $(c, d) \in \mathbb{R}^{2}$,

$$
\begin{aligned}
\left\|\mathbf{Y}-c \mathbf{q}_{1}-d \mathbf{q}_{2}\right\|^{2} & =\left\|\left(g_{1}-c\right) \mathbf{q}_{1}+\left(g_{2}-d\right) \mathbf{q}_{2}+\sum_{i \geq 3} g_{i} \mathbf{q}_{i}\right\|^{2} \\
& =\left(g_{1}-c\right)^{2}+\left(g_{2}-d\right)^{2}+\sum_{i=3}^{n} g_{i}^{2}
\end{aligned}
$$

Clearly the solution is $\widehat{c}=g_{1}$ and $\widehat{d}=g_{2}$. That is,

$$
\begin{aligned}
& \widehat{b}=\widehat{d} / \sqrt{T}=\sum_{i \leq n} Y_{i}\left(x_{i}-\bar{x}\right) / \sum_{i \leq n}\left(x_{i}-\bar{x}\right)^{2} \\
& \widehat{a}=\widehat{c} / \sqrt{n}-\widehat{d} \bar{x} / \sqrt{T}=\bar{Y}-\widehat{b} \bar{x}
\end{aligned}
$$

## The least squares estimators

By assumption $\mathbf{Y}=\boldsymbol{\mu}+\sigma \mathbf{Z}$ where $\mathbf{Z} \sim N\left(\mathbf{0}, I_{n}\right)$. In the new coordinate system,

$$
\mathbf{Z}=W_{1} \mathbf{q}_{1}+W_{2} \mathbf{q}_{2}+\cdots+W_{n} \mathbf{q}_{n} \quad \text { with } \mathbf{W} \sim N\left(\mathbf{0}, I_{n}\right)
$$

so that

$$
\begin{aligned}
\mathbf{Y} & =\boldsymbol{\mu}+\sigma \sum_{i=1}^{n} W_{i} \mathbf{q}_{i} \\
& =\left(\gamma+\sigma W_{1}\right) \mathbf{q}_{1}+\left(\delta+\sigma W_{2}\right) \mathbf{q}_{2} \quad \text { where } \gamma:=(\alpha+\beta \bar{x}) \sqrt{n} \text { and } \delta:=\beta \sqrt{T} .
\end{aligned}
$$

The representation for $\boldsymbol{\mu}$ comes from

$$
\mu=\alpha \mathbf{1}+\beta \mathbf{x}=(\alpha+\beta \bar{x}) \mathbf{1}+\beta(\mathbf{x}-\bar{x} \mathbf{1})=\gamma \mathbf{q}_{1}+\delta \mathbf{q}_{2} .
$$

Dot both sides of the last equation for $\mathbf{Y}$ with $\mathbf{q}_{i}$ to get

$$
g_{i}=\mathbf{Y} \cdot \mathbf{q}_{i}= \begin{cases}\gamma+\sigma W_{1} & \text { for } i=1 \\ \delta+\sigma W_{2} & \text { for } i=2 \\ \sigma W_{i} & \text { for } 3 \leq i \leq n\end{cases}
$$

Thus

$$
\begin{aligned}
\widehat{c} & =\gamma+\sigma W_{1} \sim N\left(\gamma, \sigma^{2}\right) \\
\widehat{d} & =\delta+\sigma W_{2} \sim N\left(\delta, \sigma^{2}\right) \\
(n-2) \widehat{\sigma}^{2} / \sigma^{2} & =\left\|\mathbf{Y}-\widehat{c} \mathbf{q}_{1}-\widehat{d} \mathbf{q}_{2}\right\|^{2} / \sigma^{2}=\sum_{i=3}^{n} W_{i}^{2} \sim \chi_{n-2}^{2} .
\end{aligned}
$$

Moreover, the independence of the $W_{i}$ 's implies that $\widehat{c}, \widehat{d}$, and $\widehat{\sigma}^{2}$ are independent random variables.

More succinctly,

$$
(\widehat{c}, \widehat{d}) \sim N\left((\gamma, \delta), \sigma^{2} I_{i}\right),
$$

so that

$$
(\widehat{a}, \widehat{b})=(\widehat{c}, \widehat{d}) R^{-1} \sim N\left((\alpha, \beta), \sigma^{2}\left(R^{-1}\right)^{\prime} R^{-1}\right) .
$$

If you look in a regression textbook you might see the variance matrix rewritten as $\sigma^{2}\left(X X^{\prime}\right)^{-1}$.

Remark. All the algebra, including the calculation of matrix inverses and a possible choice for $\mathbf{q}_{1}, \ldots, \mathbf{q}_{n}$ is carried out automatically in a statistical package such as R. There is not much point in memorizing the solutions these days.

## Chapter 14

## Moment generating functions

Formally the moment generating function is obtained by substituting $s=e^{t}$ in the probability generating function.

Definition. The moment generating function (m.g.f.) of a random variable $X$ as the function is defined as

$$
M(t)=\mathbb{E}\left(e^{X t}\right)
$$

for those real $t$ at which the expectation is well defined.
Unfortunately, for some distributions the moment generating function is finite only at $t=0$. The Cauchy distribution, which is defined by the density

$$
f(x)=\frac{1}{\pi\left(1+x^{2}\right)} \quad \text { for all } x \in \mathbb{R}
$$

is an example.
Remark. The problem with existence and finiteness is avoided if $t$ is replaced by $i t$, where $t$ is real and $i=\sqrt{-1}$. In probability theory the function $\mathbb{E} e^{i X t}$ is usually called the characteristic function, even though the more standard term Fourier transform would cause less confusion.

When the m.g.f. is finite in a neighborhood of the origin it can be expanded in a power series, which gives us some information about the moments (the values of $\mathbb{E} X^{k}$ for $k=1,2, \ldots$ ) of the distribution:

$$
\mathbb{E}\left(e^{X t}\right)=\sum_{k=0}^{\infty} \frac{\mathbb{E}(X t)^{k}}{k!}
$$

The coefficient of $t^{k} / k!$ in the series expansion of $M(t)$ equals the $k$ th moment, $\mathbb{E} X^{k}$.
$<1>\quad$ Example. Suppose $X$ has a standard normal distribution. Its moment generating function equals $\exp \left(t^{2} / 2\right)$, for all real $t$, because

$$
\int_{-\infty}^{\infty} e^{x t} \frac{e^{-x^{2} / 2}}{\sqrt{2 \pi}} d x=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{\infty} \exp \left(-\frac{(x-t)^{2}}{2}+\frac{t^{2}}{2}\right) d x=\exp \left(\frac{t^{2}}{2}\right)
$$

(For the last equality, compare with the fact that the $N(t, 1)$ density integrates to 1.) The exponential expands to

$$
\sum_{m=0}^{\infty} \frac{1}{m!}\left(\frac{t^{2}}{2}\right)^{m}=\sum_{m=0}^{\infty}\left(\frac{(2 m)!}{m!2^{m}}\right) \frac{t^{2 m}}{(2 m)!}
$$

printed: 25 November 2011

Pick off coefficients.

$$
\begin{aligned}
& \mathbb{E} X^{2}=\frac{2!}{1!2^{1}}=1 \quad \text { (you knew that) } \\
& \mathbb{E} X^{4}=\frac{4!}{2!2^{2}}=3
\end{aligned}
$$

and so on. The coefficient for each odd power of $t$ equals zero, which reflects the fact that $\mathbb{E} X^{k}=0$, by anti-symmetry, if $k$ is odd.

## Approximations via moment generating functions

If $X$ has a $\operatorname{Bin}(n, p)$ then $(X-n p) / \sqrt{n p(1-p)}$ is approximately $N(0,1)$ distributed. The moment generating function $M_{n}(t)$ for the standardized variable suggests such an approximation. Write $q$ for $1-p$ and $\sigma^{2}$ for $n p q$. Then

$$
\begin{aligned}
M_{n}(t) & =\mathbb{E} e^{t(X-n p) / \sigma} \\
& =e^{-n p t / \sigma} \mathbb{E} e^{X(t / \sigma)} \\
& =e^{-n p t / \sigma}\left(q+p e^{t / \sigma}\right)^{n} \\
& =\left(q e^{-p t / \sigma}+p e^{q t / \sigma}\right)^{n}
\end{aligned}
$$

The power series expansion for $q e^{-p t / \sigma}+p e^{q t / \sigma}$ simplifies:

$$
\begin{aligned}
& q\left(1-\frac{p t}{\sigma}+\frac{p^{2} t^{2}}{2!\sigma^{2}}-\frac{p^{3} t^{3}}{3!\sigma^{3}}+\ldots\right)+p\left(1+\frac{q t}{\sigma}+\frac{q^{2} t^{2}}{2!\sigma^{2}}-\frac{q^{3} t^{3}}{3!\sigma^{3}}+\ldots\right) \\
& =1+\frac{p q t}{2 \sigma^{2}}+\frac{p q(p-q) t^{3}}{6 \sigma^{3}}+\ldots
\end{aligned}
$$

For large $n$ use the series expansion $\log (1+z)^{n}=n\left(z-z^{2} / 2+\ldots\right)$ to deduce that

$$
\log M_{n}(t)=\frac{t^{2}}{2}+\frac{(q-p) t^{3}}{6 \sqrt{n p q}}+\text { terms of order } \frac{1}{n} \text { or smaller }
$$

The $t^{2} / 2$ term agree with the logarithm of the moment generating function for the standard normal. As $n$ tends to infinity, the remainder terms tend to zero.

The convergence of $M_{n}(t)$ to $e^{t^{2} / 2}$ can be used to prove rigorously that the distribution of the standardized Binomial "converges to the standard normal" as $n$ tends to infinity. In fact the series expansion for $\log M_{n}(t)$ is the starting point for a more precise approximation result-but for that story you will have to take the more advanced probability course Statistics 330 .
